THE

CYCLOPÆDIA

OF

PRACTICAL MEDICINE:

COMPRISING

TREATISES ON THE NATURE AND TREATMENT OF DISEASES, MATERIA MEDICA AND THERAPEUTICS MEDICAL JURISPRUDENCE, ETC., ETC.

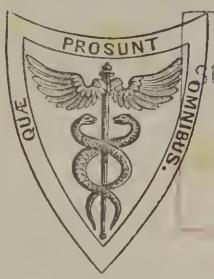
EDITED BY

JOHN FORBES, M.D. F.R.S.
PHYSICIAN TO THE QUEEN'S HOUSEHOLD, ETC.

ALEXANDER TWEEDIE, M.D. F.R.S.
PHYSICIAN TO THE LONDON FEVER HOSPITAL, AND TO THE FOUNDLING HOSPITAL, ETC.

JOHN CONOLLY, M.D.
LATE PROFESSOR OF MEDICINE IN THE LONDON UNIVERSITY, PHYSICIAN TO THE HANWELL LUNATIC ASYLUM, ETC.

THOROUGHLY REVISED, WITH NUMEROUS ADDITIONS, BY



ROBLEY DUNGLISON, M.D.
PROFESSOR OF INSTITUTES OF MEDICINE IN JEFFERSON COLLEGE, PHILADELPHIA, LECTURER ON CLINICAL MEDICINE AT THE PHILADELPHIA HOSPITAL, ETC.

'Hæc demum sunt quæ non subgessit phantasiæ imaginatricis temeritas sed phænomena practica edocuere."—SYDENHAM.

THE

CYCLOPÆDIA

OF

PRACTICAL MEDICINE.

INFLUENZA. (*Epidemic Catarrh.*) The disease now commonly known by this name, first given to it by the Italians, was not particularly noticed by physicians before the sixteenth century. Since that period it has many times appeared in Europe and in other quarters of the globe. Influenza seems to bear the same relation to ordinary catarrh that epidemic cholera bears to the common or sporadic cholera that occurs every year. Of all epidemic diseases it is the most universal; and the rapidity of its march and extent of its range over land and sea, sometimes in both hemispheres and in different climates, in opposite seasons and in all varieties of weather, among people of all classes, naturally led to the supposition that some extraordinary *influence* could alone give rise to such a wide-spreading malady. The French call it *la grippe*, under which name Sauvages first described the epidemic catarrhal fever of the year 1743.

To collate the various accounts of any one visitation of this epidemic, such, for example, as that of 1775, or of 1782, or of 1803, in order to deduce some general principles respecting its mode of propagation, pathology, or treatment, would occupy a considerable treatise: it must, therefore, be an elaborate task to draw general conclusions from all the records we now possess of this singular disease, and to condense them in a space suitable for a work like the present. Limited by this circumstance, we shall take a brief survey, first, of the most remarkable dates of its appearance and progress in the last three centuries; secondly, its symptomatology; thirdly, its treatment; fourthly, facts and general inferences relative to the causes of it, such as phenomena of the weather and diseases among brutes: fifthly, its contagious property; and, sixthly, its influence on other diseases, and connection with diarrhœa, dysentery, and cholera.

1. We find no medical description of the epidemic catarrhal fever before the year 1510. "It was called *coccoluche*, because the sick wore a cap close over their heads." The symptoms of the disease, as it then occurred, nearly resembled those which it has assumed in later visitations, namely, severe pain over the eyes, sneezing, coryza, heaviness, difficulty of breathing, hoarseness, loss of strength and appetite, fever and harassing cough. Schenk says that physicians then looked upon it as a new disease. Its course seems to have been in a north-westerly direction, from Malta to Sicily, Spain, Italy, Germany, France, and Britain; and Short says that "it attacked *at once*, and raged over all Europe, not missing a family, and scarce a person, and that none died except some children. In some it went off with a looseness; in others by sweating. *Bleeding and purging did hurt.*" (Short's Chronol. Hist. of the Weather, &c. vol. i. p. 204; and Dict. des Scien. Méd. Art. *Grippe*, p. 351.)

In 1557, an epidemic of the same nature prevailed in different countries. Fonseca says that in this year it infested Asia, thence came to Constantinople, and having spread itself all over Europe, afterwards attacked America, its course being westerly. Mercatus asserts that "before the beginning of autumn 1557, it attacked all parts of Spain *at once*, so that the greatest part of the population in that kingdom were seized with it almost on the same day." (See Report, by Dr. Glass, in Lettsom's Memoir of Dr. Fothergill, 4to. p. 625.) Riverius has transmitted to us an account of this epidemic. Unlike that of 1510, it was fatal to many: in a small town near Madrid, Mantua Carpentaria, bleeding was said to be so fatal that two thousand patients died after it in September. (Short's Hist. vol. i. p. 223.) At Alkmaer, in Holland, two hundred died of it in October.

The catarrhal epidemic fever of 1580 was distinguished by its complication with malignant fever or plague, as related by Forestus and Sennertus. (Dict. *ut supra.*) The latter speaks of its ravages at the end of summer and the beginning of autumn all over Europe; in some parts of which, as in Paris, it was the *precursor* of the plague. (Webster's Hist. of Epidemics, vol. i. p. 263.) It was in Sicily in June, at Rome in July, in August at Venice and Constantinople, in September in Hungary and Germany, in October on all the Baltic coast, in November in Norway, in December in Denmark, Sweden, Poland, and Russia; its course being from E. and S. to W. and N. (Short's Hist. vol. i. p. 262.) Mercatus says that it raged also in Spain, and destroyed not a few. (*Dr. Glass*, ubi supra.) Grand Cairo lost a prodigious multitude the same year by the plague. It is a remarkable fact, and ought not to escape our notice, that France appears to have been the only country in Europe affected that year by the plague; and it appears also to have been the first to be visited by the epidemic catarrh, its precursor; so that Buldutius even dates its origin from France. (Short's Hist. i. 262.)

The influenza of 1658, of which Willis has left us an account, visited Europe and this kingdom *suddenly* in April, and after excessive heat

in August was followed by a fatal epidemic fever. (Short's Hist. vol. i. p. 331; and Webster's Hist. 310.)

Sydenham and Etmuller have described the epidemic catarrh of 1675, which began in Germany in September, and in England in October. Malta was afflicted by the plague the same year, from which it remained free till the last severe visitation of this scourge in 1813.

The epidemic catarrhal fever which raged during the autumn and winter of 1729, in the space of five months' time visiting almost every part of Europe, was very fatal in many large cities, such as Paris and London. Loew says that in the latter more persons died than at any one time since the plague of 1665, about one thousand being cut off weekly in September. In the beginning of winter it reached France. A few weeks after, it visited the upper part of Italy with great mortality. In February it afflicted Rome and the Rhine. Turin and Milan suffered extremely. It reached Naples in March, and after this disappeared.—(*Short*, ii. p. 54. *Hoffmann*, Opera, tom. ii. p. 109.)

The influenza of 1732–3 is described in the second volume of the Edinburgh Medical Essays, and by Huxham; and was so far remarkable that it affected the mucous membrane of the alimentary canal as well as that of the organs of respiration. It spread over all Europe, and appeared also in America. It was first noticed about the middle of November in different parts of Germany. Edinburgh appears to have been the first place attacked in Britain, viz. on the 17th of December, and it raged at the same time in Switzerland, at Basle. It appeared at London and in Flanders the first week in January; towards the middle of the same month it reached Paris, and Ireland towards the end. Cornwall and Devonshire were visited about the beginning of February; few only were attacked at Plymouth, where Huxham practised, so soon as this: but in March it prevailed on all sides. In February Leghorn was attacked, and near the end of it Naples and Madrid suffered. New England in America was invaded by the distemper about the middle of October, which travelled southward to Barbadoes, Jamaica, Mexico, and Peru, much at the same rate as it had done in Europe. It appears to have been at Paris early in the year. "Elle se manifesta, dit de Jussieu, à la suite de brouillards fétides, plus épais que les ténèbres de l'Egypte." (Edinb. Med. Essays, vol. ii. p. 31. *Huxham*, de Aere, &c. tom. i. Dict. des Scien. Méd. art. *Grippe*.)

The epidemic catarrh of 1733 was followed by those of 1741 and 1742; the first described by Haller, and the second by Sauvages and Huxham. In 1743, towards the end of April, Huxham says that it was general in England, and in the spring spread over all Europe under the name of "influenza," or "grippe." This epidemic was the *precursor* of the plague of Messina in Sicily the same year; and it was more fatal in the southern parts of Europe than in England, though it increased the deaths in London in one week to a thousand. (De Aere, &c. tom. ii. p. 104.)

The next remarkable visitation of the influenza was in 1762; and an elegant description of it is given by Sir George Baker, "De Catarrho Epidemico anni 1762," who records its appearance in London about the 4th of April. Razoux, a physician of Nismes, has given an account of the same disease, which was epidemic in Europe generally in the spring. (Dict. art. *Grippe*.) It attacked Breslau at the end of February; Vienna was visited in March, and Hamburg in April. In Venice it was more fatal than in other places. It spared, however, Paris and the greatest part of France; nor can we find any particular cause for this exemption. Nismes most probably was visited; and Webster says that "Toulon lost one third of its inhabitants by an epidemic in 1761." The influenza of 1762 appeared sooner in London than in any other part of England, namely, the beginning of April. It was not observed in Edinburgh and Dublin till May; but in June it was general and severe, according to Sir G. Baker, being seen no where earlier than February nor later than July. It had prevailed in America the preceding year. (Webster's Hist. i. p. 410.) It was not till July that it attacked the British sailors in the Mediterranean. It was immediately followed in London by an epidemic dysentery, which raged till November. While the influenza prevailed, the deaths in London scarcely exceeded the usual number. In Manchester they were even fewer than common; and at Norwich far more died of it than fell victims to the *more severe* influenza of 1743. (*Baker*, de Catarrho, p. 33.)

The next epidemic catarrh, in order of time, was that noticed in London and different parts of the nation by Dr. Fothergill and some of his friends in the latter end of the year 1775. It was observed also in France, Holland and Germany, and was supposed to be more fatal in those countries than in Britain. (Lettsom's Memoir of the Life of Fothergill, 4to.; and Med. Obs. and Inquiries, vol. vi.)

The influenza of 1782 was general over England, Scotland, and Ireland, between the months of May and July inclusive. A full account of it is given in the second volume of Memoirs of the London Medical Society, by Dr. R. Hamilton, which is the groundwork of the article "Influenza" in the Edinburgh Medical and Surgical Dictionary; an account is also given in the first volume of Medical Communications by Dr. Gray, compiled from papers in the British Museum, which is the basis of a like article in the Cyclopædia of Dr. Rees. (See also the third volume of Transactions of the College of Physicians, London.)

The influenza of 1782 seems to have pursued a course from the east, not very different from that of the epidemic cholera which is now (1832) displaying its ravages in Great Britain and France. It is reported to have broken out in September 1780, and to have become very general in the crew of the Atlas East Indiaman, whilst that ship was sailing from Malacca to Canton. When the ship left Malacca, there was no epidemic disease in the place; when it arrived at Canton, it was found that at the very time when they had the influenza on board the Atlas in the China seas, it had raged at Canton with as much violence as it did in London in June 1782, and with the very same symptoms. In October and November 1781 it appeared in the East Indies, and

was said to have attacked the British army while it was besieging Negapatam in November 1781. Its progress is stated by Webster, to have been from Siberia and Tartary westward. At Moscow it prevailed in December 1781; at Petersburgh in February 1782; and it was traced to Tobolski. It was in Denmark in the latter end of April. From the shores of the Baltic it spread to Holland and the Low Countries, and thence to England. London was said to be attacked sooner than the west and north; Ireland a few weeks later, and the south of Europe later still; for it prevailed in France in the months of June and July, in Italy in July and August, and in Portugal and Spain in August and September; seldom continuing longer than six weeks in any place.*

The influenza of the spring of 1803 afforded an occasion for collecting a great number of notices from different parts of the country on the subject of this epidemic. The London Medical Society set a laudable example by proposing a set of queries to its corresponding members in a circular letter; and the sixth volume of "Memoirs" contains reports from nearly sixty practitioners in England, Scotland, and Ireland, as to the date of its first appearance, its symptoms, treatment, &c. in their respective neighbourhoods. Dr. Beddoes also interested himself very zealously on the same occasion, and procured various testimonies from his friends and others, which, to the number of one hundred and twenty-four, are inserted in the ninth and tenth volumes of the "London Medical and Physical Journal." These documents contain a mass of very useful information. This epidemic was observed at Paris and in other parts of France and in Holland some weeks before it appeared in London; and Dr. Bardsley says "the same length of time was occupied in its progress from the latter city to Manchester." (Med. and Phys. Journ. vol. ix. p. 529.) Its course seemed to be from S. to N. It was in Cork and Dublin before it reached the north of Ireland, immediately after a S. E. wind. An epidemic ophthalmia followed it in France, (Dict. *ut supra*,) and a severe dysentery, such as had not been known for thirty years, in some parts of the United States, which it visited the same spring. (New York Med. Repos. 2d Hex. vol. ii. p. 141.) It was observed to be *epidemic* in Sussex, and some of the counties in the S. W. as early as February; in Shropshire, Nottinghamshire, &c. in March; in Yorkshire and Lancashire in April; and at Sunderland in May. (Mem. of Med. Soc. of London, vol. vi.) It was evident that there was a degree of progressive movement northward, by marking the time when it was at the height in each place; yet many of the accounts above alluded to inform us clearly that sporadic or solitary cases exhibiting the true characters of influenza, occurred in several places long before the disease became established, so as to manifest a universal tendency to that form of complaints over the country, in some cases weeks before it was quite developed. It is worthy of notice that this has been remarkably the case with the epidemic cholera. Dr. Gray observes that, in 1782, a complaint, similar to the influenza, was taken notice of in some parts of the kingdom *several months* before that disorder made its progress through it. (Med. Commun. vol. i. p. 6.)

The influenza of last year (1831), though generally mild in its character, was almost universal; for it would seem to have prevailed in both hemispheres in the same year. Accounts have been received of its appearance in India as well as in the United States of America. (American Journ. of Science, &c. vol. xxi. No. 44, p. 407.) In many places it has been the precursor of the epidemic cholera. About a month before the latter disease broke out in Warsaw, it prevailed in that city. (Brierre de Boismont sur le Cholera, p. 110.) It also swept over great part of England, Scotland, and Ireland, in the spring and autumn, and preceded the *milder* visitation of epidemic cholera which many parts of Great Britain experienced the same year. Late in the autumn it attacked Paris, the south of Spain, Gibraltar, and Italy, with more severity than it did the British islands. At Rome it was said to occasion great alarm. It has certainly skipped over many countries of Europe in its march from Poland to France through England, so far as we can judge negatively from the want of official reports; but, with this exception, it has pursued a course not widely different from that of similar former epidemics, and has proved to be a true herald of the epidemic cholera in many places.

[In the epidemic of 1831, according to Most, (art. INFLUENZA, in *Encyclop. der gesammt. Medicin. und Chirurg. Praxis*, Leip. 1836,) 30,000 people, it was asserted, were suffering at the same time in Berlin; and, at a later period, 45,000 in Paris. Another severe epidemic prevailed in Europe and the United States in 1837; and another in 1843. Of the European epidemics of 1831, 1833, and 1837, the two first were less severe, and attacked fewer individuals than the last.]

II. The influenza does not seem to have exhibited a greater variety of symptoms, in its different visitations, than other epidemics. It has varied a little in town and country, in spring and autumn, at the beginning and end of the epidemic, in different persons, and according to the particular *genus* or tendency of the epidemic constitution; but still it has maintained some prominent characteristics of its identity at different periods. The ordinary course of the disease has been marked by the following symptoms:—it usually commenced with slight chills, amounting sometimes to shiverings, and alternate flushings of heat, with languor and sense of extreme weariness: then, soreness over the eyes, or pain in the course of the frontal sinuses: these were quickly followed by frequent sneezing, a copious discharge of lymph or thin clear fluid from the nose and eyes, sometimes so acrid as to excoriate the upper lip; heat and soreness in the top of the larynx and œsophagus, and along the course of the windpipe, with hoarseness and dry cough; sense of stricture in the chest and difficulty of breathing, sometimes attended with darting pain in the muscles subservient to respiration; weight and anxiety about the præcordia, flying pains in the back, knees, calves of the legs, and various parts of the body; depression of spirits, and sudden

* Transactions of the College of Phys. vol. iii., and Med. Communications, vol. i. Rees' Cyclopædia, Art. *Influenza;* and Trotter's Med. Nautica, i. 362. Observations on Dis. of Seamen, by G. Blane, M. D. p. 151.

and extraordinary prostration of strength. The tongue was mostly covered, at an early period of the complaint, with extremely white mucus, like cream—a symptom particularly noticed by Huxham, Baker, Pettit, and others: there was loss of appetite, the thirst was inconsiderable, and the pulse generally quick, weak, and soft.

The preceding symptoms appeared in various degrees and combinations, as the violence of the disease fell more particularly upon the mucous membrane, in the head, in the throat and chest, or in the stomach and bowels. When the disease chiefly affected the head, vertigo, violent headach, greatly increased by the cough, and delirium, were not unfrequent: there was hemorrhage from the nose, and pain in the ears; from which, in one case, a clear fluid was poured out like that from the nostrils. (Med. Trans. of the College of Physicians, vol. iii. p. 69.) In some rare cases the tonsils and back part of the throat were inflamed, so that suppuration was the consequence. When the violence of the disease fell upon the lungs, as in old people, asthmatic patients, and those predisposed to phthisis, hemoptoe was not uncommon, and frequent troublesome cough which prevented sleep. It often degenerated into pleurisy and peripneumony. In common cases the cough became loose in three or four days. The stomach was affected with nausea in many, and vomiting in some; and a spontaneous diarrhœa relieved both head and lungs, and speedily cut short the complaint. But in many instances, and in several visitations of the epidemic catarrh, a morbid determination to the intestinal canal was manifest from the beginning; which, so far from being considered a salutary effort of nature to relieve the system in that way, required especial care in the treatment, and the utmost caution in the use of purgatives. The fever was generally mild in the day-time, and it increased in the evening; and it seldom abated till some critical amendment took place by perspiration or otherwise. There was little remarkable in the urinary secretion. The duration of the complaint was from a day or two to a week or fortnight. In some, the symptoms, after abating in two or three days, returned and raged with violence. The far greater part had critical sweats about the third day, which, attended with free expectoration, banished the fever on the fifth day. One of the most remarkable features of influenza is the debility; so that many could not rise from the horizontal posture without sudden faintings, even in the state of convalescence; and the debility often remained for a considerable time. The suddenness of the invasion, the pain and tightness in the forehead, with pain in the back, knees, and muscles, and singular prostration of strength, were thought to be distinguishing marks between the influenza and common catarrh. Indeed, the pain or soreness in the face, temples, and cheekbones, was considered the most certain pathognomonic symptom in 1782; "and now and then was felt previously to the catarrh, and not unfrequently was followed by very little or no catarrhal affection."

In one district in Gloucestershire, a practitioner states that "in no two persons in 1803 did he observe precisely the same symptoms." (Med. and Phys. Journal, vol. x. p. 309.) If this was the case, the symptoms might be expected to vary considerably in different places, as well as in different visitations of the distemper. And this has happened accordingly. The rarer occurrences were, an unusual disposition to sleep, strangury and bloody urine independent of blisters, *peculiar slow and strong pulse*, with excessive debility, as at Newark; ringing in the ears and abscess, and abscess in the frontal sinus; of which last Dr. Rush had three cases in 1790. (Trans. of Col. of Phys. iii. 68, and Rush's Med. Inquir. ii. 354. Mem. of Med. Soc. vol. vi. p. 383.)

The duration of influenza in any one place seldom has exceeded six weeks. Upon the whole few have died of this complaint, although it has often attacked more than one-half or even three-fourths of a whole community. The chief victims have been the aged and asthmatic, those of tender lungs and of full oppressed habits. Those of middle age were more liable to be affected than old persons and children; and persons exposed to the air than those who were confined. Many recovered their strength very slowly, and some, especially in 1762, fell into incurable consumption.

[Some epidemics have, however, proved extremely fatal. The mortality of the epidemic of 1837 in Europe was greater than that from cholera, although the disease was by no means so severe, or so rapidly fatal. This was owing to its attacking almost every one, whilst the ravages of cholera were comparatively limited. It has been estimated by Dr. Graves (*Clinical Lectures*) that in Dublin alone, 4,000 persons died of the influenza of 1837.]

III. One general observation seems to apply to almost every epidemic disease, including even those of a pestilential nature, viz. that during its prevalence numbers are attacked in so slight a manner as to require but little medical care. Hence the influenza, which in all its visitations has had a favourable character in the majority of cases, has been easily removed by mild diluents, rest, and abstinence for a few days from animal food and fermented liquors. Besides this, a complaint so various not only in its symptoms but in the degrees of their intensity, modified too at different periods by season, climate, and epidemic constitution, would of necessity call for the exercise of much discretion in the employment of remedies. But, making due allowance for all this variety of character in the complaint, and for the judicious adaptation of a corresponding treatment, physicians of eminence, in different countries, seem to have agreed remarkably in their testimony as to the general rules and principles of their practice; and from the very beginning of the sixteenth century, in their reports, with respect to bloodletting, to the caution about active purgatives, to the employment of a cold regimen, and to the restricted use of opiates, there is a very striking and satisfactory coincidence.

In the mild attacks of the disorder, few if any medicines have been required. In severe cases emetics at the beginning relieved the sufferings of the head and chest, and, combined with gentle aperients and antimonial or saline medicines, were found useful in mitigating the fever and promoting a salutary diaphoresis.

No observation is to be found more general in practical writers in this disease than that bloodletting could rarely be employed with safety, far less with benefit, on account of the alarming debility and weakness of the pulse; and when it was strongly indicated, practitioners were sparing in the quantity of blood, and cautious in repeating the remedy. In the epidemic of 1510, Dr. Short tells us that "bleeding and purging did harm." In 1557, bleeding was said to be so fatal, that in a small town near Madrid two thousand persons died after it in September. In 1580, Sennertus ascribes the death of two thousand persons in Rome to venesection, and states that, where it was omitted, the mortality was not greater than one in a thousand. "Experientia enim hoc comprobavit, omnes fere mortuos esse, quibus vena aperiebatur." Forestus, in his Scholia on the same epidemic, suggests a good practical hint, that we ought to distinguish very carefully those cases which might require, from those which might not bear this remedy. Huxham, who had no prejudice against bloodletting, remarks, "Imo, si vel peripneumoniæ aliquid subesset, minime largam, sine maxima virium ruina, plus vice simplici venæsectionem tolerabat: *nec in hac solum, sed in omni febre catarrhali epidemica hoc fere perpetuum notavi.*" (De Aere, &c. ii. 102.) In Edinburgh it was noticed that those who were bled, in 1733 and 1782, "recovered more slowly;" though others at the commencement seemed to be relieved by the lancet. (Med. Essays, vol. vi. p. 29.) In the influenzas of 1733, 1775, and 1803, in France, bloodletting was generally injurious. (Dict. des Sc. Méd. *Grippe*, pp. 356, 359, 363.) Dr. Glass reports that at Exeter, in 1775, venesection "weakened the patient without relieving the pain;" and Dr. Ash considered that "it was never necessary to bleed at Birmingham; that in a neighbouring town, three died who were bled, and all recovered who were not bled." (Lettsom's Mem. of Dr. Fothergill, 4to. p. 627.) Dr. Gray gives it as a general inference from the accounts transmitted to a "Society of Physicians" in 1782, "that bloodletting was by no means conducive to the general cure of the disease." (Med. Com. vol. i. p. 80.) Many physicians bear testimony to the same good rule of practice in the influenza of 1803, as Dr. Bardsley of Manchester, Dr. Kinglake of Taunton, Dr. Rutter of Liverpool, and others. (Med. and Phys. Journ. vol. ix. and x.) Notwithstanding the foregoing authorities, it is admitted by some eminent physicians, that cases now and then occurred in which this remedy was useful. Sir George Baker made this observation in 1762, in London (p. 29); and in the same city it is somewhat remarkable that in the epidemic of 1775 it was less hurtful than in other places, which was perhaps owing to the more frequent complication of the disease that year with pleurisy and peripneumony, at all times no unusual circumstance.

Opiates at the commencement of the disease almost invariably increased the febrile heat, aggravated the headach, in some cases even to delirium, tightened the chest, and stopped the expectoration: but in the decline they proved salutary. A cool temperature, both in drinks, in the air of rooms, and in the quantity of bed-clothes, was found to be useful; while, on the contrary, warm rooms hot drinks, and cordial sudorifics, aggravated the violence of the disorder. Blisters to the chest, sides, or back, often greatly relieved the stitches and cough; and ipecacuanha was much extolled, especially in France, for its efficacy, when given in small doses, in assisting expectoration, relieving the oppressed lungs, and correcting the tendency to irritation of the mucous membrane of the bowels. A medicine often used with good effect to ease the cough when attended with viscid phlegm, was the solution of gum ammoniac combined with oxymel of squills. When recovery was tedious and the strength much impaired, even long before the cough was removed, some bitter infusion, such as that of calumba, cascarilla, or Peruvian bark, with wine-whey and some nutritious diet was of great service. The reason why purgatives have been so generally reprobated by practitioners in the influenza, appears to have depended on the fact, that a morbid state of the mucous tissue of the internal surfaces exposed to the air, was often closely connected with a morbid tendency in that of the alimentary canal; and, therefore, drastic purgatives, though they might relieve one system or set of organs, yet too often only transferred the disease, as it were, to another, and produced a dangerous debility.

[Lobelia inflata was recommended by Dr. Cartwright of Natchez, (*Medico-Chirurg. Rev.* for April, 1837, p. 586,) for the not very cogent reason, that "in those diseases affecting the mucous lining of the bronchial tubes, the lobelia inflata comes as near being a specific [?] as tartar-emetic and the lancet in pneumonia and pleurisy." Lobelia, as elsewhere said, (*Practice of Medicine*, 2d. edit. i. 263, Philad. 1844,) is certainly a valuable sedative, but not deserving of the elevated rank that has been assigned to it. The diseases of the bronchial tubes differ, and no one remedy can be applicable to every pathological condition. When there was more than usual inflammation of the bronchia, in the epidemic of 1837, large doses of the ethereal tincture of lobelia, repeated at short intervals, with counter-irritation, seemed, according to Dr. Blakiston, to be useful.]

IV. Among the phenomena relating to the weather, which seem to have had a connection with epidemic catarrh, either as precursor or attendant signs, we may notice extraordinary vicissitudes, easterly winds, thick or offensive fogs, and diseases, often of a similar kind, among horses, dogs, and cattle. Epidemic catarrh is a disease either of spring or autumn. The spring influenzas have sometimes occurred when the first heat suddenly followed the winter's cold; and the autumnal, when the cold moisture and raw fogs of November have succeeded to the heat of a dry harvest; yet there has not been a uniform connection between any one sensible quality of the atmosphere as to heat or cold, rain or drought, wind or calm, and the prevalence of this epidemic; for in different places it has maintained itself under the dominion of each of these states of the weather, "et tempori frigidiori et calidiori, et flante tam austro quam Borea, et pluvioso et sereno cœlo, peragravit hasce omnes Europæ regiones, et omnia loca indiscriminatim." (*Salius Diversus*, cited by Dunning, Med. and Phys. Journ. x. p

143.) In fact, extraordinary vicissitudes have been more remarkable than any thing else: in some places, one peculiar sign of atmospheric intemperature has been observed, and in other places a different sign; and the epidemic has frequently fallen capriciously or partially, like the blight over a country, or even over a garden.

Short says that "thick, ill-smelling fogs preceded, some days, the epidemic catarrh of 1567. July, August, and September had been very hot and dry; and in the end of September came a very strong cold north wind." (History, &c. vol. i. p. 223.)

Riverius, quoted by Saillant in his History of Catarrhal Epidemics, says that just before that of 1580 appeared in France, (at Nismes or Montpelier?) "a prodigious quantity of insects appeared in April and May; and the roads were covered with them in such a manner, that a person in walking might have destroyed them by thousands." (Dict. des Sc. Méd. tom. xix. p. 359.) And Petrus Salius Diversus, cited by Dunning, tells us of the birds and brute animals suffering generally the same year. (Med. and Phys. Journ. x. 143.) To these facts we may add the observation of Short, that "after a long continuance of hot, moist weather, attended with southerly winds, at the rising of the dog-star came a cold, dry, north wind; and from the middle of August to the end of September raged the malignant epidemic catarrh." (Hist, &c. i. p. 260.) Great extremes of the weather preceded the epidemic catarrh of spring 1658, decribed by Willis, (Ibid.); and Sydenham attests that "the epidemic catarrh of autumn 1675 immediately succeeded cold and moist weather, which suddenly followed an unusually warm summer." (*Syd.* Opera, sect. v. ch. 5.)

We have no very particular account of the state of the weather in England attending the epidemic catarrh of autumn 1729; but Hoffmann does not hesitate to ascribe its origin in Germany to the uncommon "irregularity and frequent changes of the weather from heat to cold and from cold to heat, &c. which distinguished that and the preceding year, such as he had never before witnessed; causing throughout all Germany, Belgium, England, and elsewhere, unusual sickness: "tam uberi proventu enati fuerint morbi, quam vix alio tempore visum unquam." (*Hoffmann*, Op. tom. ii. pp. 83, 109.)

Within the last century the number of observations on the phenomena in question increases very considerably; and we are thus enabled to make some approximation to general principles. Saillaint's excellent work, (Tableau des Epidemics Catarrhales, depuis 1510, jusque celle de 1780), on the continent, and the facts which have been collected in this country, on the catarrhal epidemics of 1775, 1782, and 1803, afford us much assistance in this inquiry.

De Jussieu says that "the influenza of spring 1733 appeared in France immediately after offensive fogs, *more dense than the darkness of Egypt*," (plus épais que les ténèbres de l'Egypte. (Dict. Art. *Grippe*.) Huxham remarks generally that the cause of epidemic catarrh seems to depend on a thick, moist, and cold air; and that in the autumnal months preceding the spring catarrh of 1733, epidemic diseases were very common and fatal among horses. (De Aere, &c. tom. i. pp 73, 75.) We find, also, that about Edinburgh coughs and running from the nose in horses were universal in October and November, just before the disease attacked men. (Med. Essays, ii. p. 31.)

The influenza of spring 1743 was the precursor of the great plague in some parts of Sicily. In England it was not so severe and fatal as in some other parts. About Plymouth, according to Huxham, many horses were diseased, and deer perished in January. (Webster's Hist. i. 386; and Huxham, op. cit. ii. p. 95, &c.)

Sir G. Baker says that the weather in spring 1762, before the epidemic catarrh of that year broke out in London, was extremely irregular; wind, frost, snow, and rain following each other in rapid succession, and with unusual severity. In April and May, intense heat followed; and beside this, the air underwent very sudden changes from heat to cold and from cold to heat. (De Catarrh. Epid. p. 7.)

A hot dry spring and summer preceded the epidemic catarrh of autumn 1775. Petit says that in France the disease was ushered in by thick noisome fogs ("brouillards fétides"), and a cold rainy autumn. (Art. *Grippe*, Dict. p. 359.) Dr. Anthony Fothergill says that disease among dogs and horses was general over England before the influenza broke out, (Mem. of Med. Soc. vol. iii. 36); and we are also assured that it was preceded by foggy air as well as by disease among dogs and horses in Dorsetshire, and at Exeter; and by unusual haze, easterly winds, and almost universal cough among the horses in North Wales. (See the Reports of Drs. Pulteney, Glass, and Haygarth, in Lettsom's Life of Fothergill.) About the 7th of October, 1775, it appeared in the shire of Galloway in Scotland; "and a continual dark fog and particular smoky smell in the atmosphere prevailed for five weeks, the sun was seldom seen, and though October and November are particularly rainy months in that country, little or no rain fell, the wind E S E. and S." (Mem. of Med. Soc. vol. vi. p. 323.)

With regard to the influenza of spring 1782, "the spring of this year was remarkably late, with a long prevalence of cold easterly winds; the hedges were not full blown in Cornwall before the beginning of June. A similar state of weather has commonly ushered in this universal malady." (Trotter's Med. Naut. vol. i. p. 362.) Dr. Hamilton tells us that "from the first of January till the end of May, throughout most places in the kingdom, the weather was uncommonly unfavourable;" and it appears that the latter month "*was remarkable in all the meteorological annals of Europe for its unusual degree of cold and humidity, with a gloomy and uncommonly disturbed state of the atmosphere.*" (Mem. of Med. Soc. vol. ii. p. 433 and 445.) Dr. Darwin adds his testimony, that in this year (1782) "the sun was for many weeks obscured by a dry fog, and appeared red as through a common mist:" and he supposes, "the material which thus rendered the air muddy, probably caused the epidemic catarrh which prevailed in that year." (Zoonom. c. ii. 1, 3.) Dr. Parr says that horses were affected with a cold at the same time, near Exeter. (Med. Comment. vol. ix. p. 414.) Maertens records a strik-

ing fact relative to the first appearance of this epidemic at Petersburg, and its connection with a particular change of the weather: "On a cold night the thermometer rose 30° of Fahrenheit; *the next morning* forty thousand people were taken ill with the influenza." (Med. and Phys. Journ. vol. x. p. 524.)

The influenza of spring 1803, as we have said, afforded an occasion for the collection of many valuable observations. It appeared in France some weeks before it invaded this country, and was supposed to be owing to a cold and humid autumn succeeding a dry and hot summer. At Paris it was immediately followed by a severe epidemic ophthalmia, about the time the influenza first appeared in Britain. (Dict. ubi supra.) With respect to unusual extremes in the weather, such are stated to have occurred in Hampshire, London, Somersetshire, and St. Andrews in Scotland, (Med. and Phys. Journ. x. 313, and Mem. of Med. Soc. vol. vi.) "I am of opinion," says Cuming, (Romsey, Hants,) "that the remote causes of this disease originated in the sudden change of atmosphere, a change, I believe, generally felt *throughout the United Kingdoms*, as well as upon the continent." Epizootic diseases preceded it, in some places among one or two species of animals only, in others among several, as cats, dogs, horses, cows, sheep, swine, in Shropshire, Worcestershire, Staffordshire, Cumberland, Hampshire, Lancashire, &c. (Ibid. pp. 288, 379, 316, 414, 426, 444, 482, 576.) At Plymouth "many attributed the disorders among the horses to their having eaten insects, which for many weeks were innumerable, and covered the fields in a most extraordinary manner whorever there was any length of grass; and this, from the mildness of the season, was general in almost every field." (Med. and Phys. Journ. x. 137.)

Disease was very prevalent among sheep in some parts of the north of England, last spring (1831), just before the influenza appeared; and an epidemic catarrh seems to have raged among horses in the south later in the year. The influenza of this year was remarkable for this, that it prevailed in some parts of Great Britain in spring, and in other parts in autumn. Its character was generally mild in all. With regard to the weather, an intelligent captain of a regular trader in the English channel declared to the writer of this article, that for thirty years past he had no recollection of such a long continuance of a thick and foggy atmosphere, as he has had occasion to observe within the last eighteen months, between this country and the south of Ireland. He went so far as to state that he had scarcely made one clear passage from Liverpool and back again during this whole period.

One general inference offers itself to our notice on reviewing the foregoing facts, viz. that no particular phenomenon in nature universally characterizes the epidemic constitution which precedes, or that which accompanies the disease called influenza; and we are led to conclude that the causes of this epidemic, supposing them to take their rise in atmospherical changes of a universal nature, are far from being marked by uniformity in the signs At the same time we are bound to admit that the changes from warm weather to cold, and from cold weather to warm, with dampness, fogs, and easterly winds, have rarely been absent from the catalogue of natural indications. Disease among domestic animals is also to be noted as a very common precursor in many places, and in several distinct visitations of the influenza.

[Dr. Graves (*op. cit.*) suggests that the disease may depend chiefly on telluric influence, or upon some agency connected with variations in the physical conditions, which operate on the external surface of the earth. The suggestion only indicates the little knowledge we have of the subject.

In regard to the nature of the disease, various opinions have been entertained. Essentially it consists of the collection of symptoms to which the names of catarrh and bronchitis are applied; but along with these, especially in the influenza of 1837, the nervous system has been implicated. By one of the writers on the epidemic, Dr. Blakiston, it has been designated "an affection of the nervous system, with its concomitant derangement in the organs of digestion, and circulation commonly known under the name of nervous fever, accompanied throughout its whole course by irritation of the pulmonary mucous membrane," and this view seems to have been embraced by most writers on the subject. Andral, however, (*Cours de Pathologie Interne*,) concludes that it is a general affection, the nature and cause of which are as unknown as those of the greater part of epidemics, which appear at irregular epochs.]

V. The influenza, like every other epidemic disease, has given occasion to medical observers to entertain very opposite views on the question of its contagious property. Were we to draw a general inference from the recorded statements of the majority, we should say that it was *not* contagious; for the numbers who have given an opinion on this side far exceed the advocates of contagion. But we must not appeal to the majority in order to decide a principle in science. It must, however, be acknowledged, that while individual or partial occurrences might lead to the supposition that influenza was propagated in many instances by contagious transmission, a comprehensive survey of facts goes far to establish the contrary opinion; for some things can hardly be explained on the principle of contagion without having recourse to suppositions that could not be warranted by a sound induction. Upon the whole it would appear that some general cause, if not originating, at least subsisting in the atmosphere, and depending on its changes, progressive also in its movements from place to place and from country to country, gives rise to the disease; but that it is probable that a limited propagation *also* takes place by personal intercourse, *under the influence, and during the prevalence, of the epidemic constitution.*

We have writers affirming that persons who have been visiting or on business in an *infected* town, have been the first to introduce the epidemic into their own town or neighbourhood; and it cannot be doubted that the members of a family and the inhabitants of a district have often been attacked by the influenza *in succession.* Hence these things would seem to indicate that the disease was propagated by contagious transmission

more than by some universal medium. But the difficulty of proving the first to be actually the case, must, in the nature of things, be very considerable; for it would appear,—and the remark applies to almost every epidemic disease,—that in many places a tendency to the epidemic has been recognised by clear indications some time *before* the peculiar combination of symptoms which characterize it have shown themselves, making the moment of actual invasion very doubtful; just as, it is well known, the epidemic imprints its own character for some time *after* upon the diseases that follow it. And though no *epidemic* disease with which we are acquainted is so sudden and simultaneous in its attacks as influenza, and therefore none more emphatically deserves the name of *epidemic*, nor more decidedly proves a universal cause; yet it is a striking fact that, with all its frequent rapidity of movement over the globe, it has in almost every country been more or less obedient to the laws which govern other epidemics, according to some *progressive* and *consecutive* operations that are as much hidden as the efficient cause of attraction. It does, in fact, mostly observe some progressive law in moving over a country and in attacking a given multitude of people, which demonstrates that, however universal may be the cause of an epidemic disease in its purest form, yet if we regard experience, the effects rarely if ever should be expected to appear without some degree of consecutive order. The difference of constitution, of age, of habits, of locality, and of other things, may be quite sufficient to account for the phenomenon of successive attack; and indeed it is what we might expect *à priori*. If to this we add the probability, and, indeed, necessary inference from the facts, that the cause itself is developed gradually, we shall have less difficulty in accounting for a continuous mode of attack on another principle than that of contagion.

Though a successive mode of propagation over a country or city is most usual, yet on some occasions the spread of influenza over a whole kingdom, within the space of a few days, has been so general as to make the propagation by means of personal intercourse quite incredible, and almost impossible. Besides this, its sudden appearance in ships at sea, which have had no intercourse with land or with other vessels for a considerable time, can hardly be explained on any other supposition than that of its atmospherical origin. Dr. Anthony Fothergill assures us that "both the epidemics of 1758 and 1775 seized whole families on the same day, often remote from one another, and without any intercourse. (Memoirs of Med. Soc. vol. iii. p. 36.) Again, "the influenzas of 1775 and 1782 seized some persons at sea, while others were attacked on shore, and that without any perceptible communication." (Ibid. 38.) "The appearance of the Influenza in 1803, in England," according to Dr. Woodforde, "was very sudden, and its attack extremely general, so that it is difficult to say in what or in how many parts of the kingdom it prevailed at first. It is probable that the disease broke out in all at or nearly the same time." (Med. and Phys. Journ. vol. ix. p. 505.)

The following fact is very conclusive as to the operation of some general cause; for it is scarcely probable that contagion could be lurking a long time before, and then should burst forth at the same time in distant points in so remarkable a manner. Two separate fleets left the coast of England for different points of destination in the year 1782; one, under Admiral Kempenfeldt, on the 2d of May, to cruise between Brest and the Lizard; the other, under Lord Howe, on the 6th of the same month, for the Dutch coast: neither fleet had communication with any shore; and the crews of each were perfectly healthy on sailing from Spithead. But on the 29th of the month, near four weeks after, the crew of the *Goliah*, one of the ships under Kempenfeldt, was attacked with influenza, and about the same time the epidemic appeared also in the *Rippon*, under Lord Howe. The other ships of both fleets were attacked in succession. In fact, so many men of both squadrons, on these remote stations, were rendered incapable of duty, that all were obliged to return to Portsmouth about the second week in June. (Transactions of the Col. of Phys. vol. iii., and Trotter's Med. Naut. vol. i. 364.)

If we pay attention to the course or direction of the several visitations of the influenza, we may observe that its general progress is not without some order. It either follows a westerly course, or one from the south towards the north. If its course be westward, it does not usually take extensive leaps over kingdoms, and then return to those it may have missed, as would be likely to happen if nothing more than personal intercourse and the various casualties of travellers' routes exerted an influence in determining its course. But it sweeps along the north from the east through Russia, Poland and the north of Germany to England; and then wheels round through France and Spain to Italy. And here we cannot but trace a striking resemblance to the career of the epidemic cholera. But if influenza arises in the south, it takes a course from Italy through Spain, France, Britain and the Netherlands, along the shores of the Baltic. In the one case France is attacked before England, in the other after it.

Were we to admit that the propagation of an epidemic disease over a space of some hundred square miles in the course of a few days or weeks might be accounted for on the doctrine of contagious transmission by means of travellers and the facilities of human intercourse, analogy might supply us with an argument against the admission; for in the case of some of the domestic animals, which do not travel from country to country like man, but are comparatively stationary, epidemic diseases are observed to spread among them; sometimes in as extensive and simultaneous a manner as amongst human beings.

VI. The facts we are now to notice seem to afford strong indications of the influence which the general cause that produces epidemic catarrh exerts over the human body with regard to other diseases; and so far they are opposed to the theory that contagion is the cause of it. Webster has remarked that catarrh or influenza is the disease which is most clearly connected with pestilence in the form of malignant angina, dysentery, yellow fever and plague, which it usually precedes. (See Hist. of Epid. vol. ii. p. 39 and 48.) This ob-

servation is partly confirmed by subsequent experience. These facts also show how the general cause is controlled or modified by local peculiarities, as well as by constitutional varieties.

Sir George Baker tells us, that "while the influenza of 1762 was prevailing in a very mild and tractable form in the villages near Lincoln, that were high and exposed, quinsies, pleurisies, and peripneumonies produced incredible destruction of life in the low neighbouring districts." (De Catar, Epid. p. 19.)

Dr. Carrick of Bristol says that "one of the most open and exposed of the buildings on Clifton Hill is Richmond Terrace, which forms three sides of a parallelogram, fronting respectively the east, south, and west. On the east side, not one family, scarcely an individual, escaped the complaint (in 1803), while on the south side a great majority both of persons and families, in all other respects similarly circumstanced, escaped it entirely."—(Young's Med. Literature, p. 575. See also Mem. of Med. Soc. vol. vi. p. 345.)

Dr. Binns states that at the time the scarlatina existed at Ackworth School in 1803, the influenza prevailed in the neighbouring towns; yet that the latter did not attack a single individual of the family at the school, consisting of between three and four hundred persons." (Ibid. p. 351.) Burton-on-Trent, also, in great measure escaped the influenza the same year; and scarlatina, with hooping-cough and measles, were epidemic there *in its place.* (Ibid p. 405.)

"In London the influenza of 1803 superseded or deferred the usual diseases of the spring, as the measles and scarlatina: this is also recorded by Lorry to have been the case in the epidemic catarrh that prevailed in France in 1775; but he adds, that during the summer these complaints appeared with more than usual violence and fatality." (Ibid. p. 520.)

"At Aberdeen the influenza of 1775 began near the end of November and continued four or five weeks, but did not visit Fraserburg, *where there was a putrid fever very fatal at that time.*" (Lettsom's Mem. of Fothergill, p. 642.) At Chester, according to Dr. Haygarth, "the same epidemic, in 1775, attacked many who were confined to their houses and even to their beds with other ailments." (Ibid. 637.)

Dr. Vaughan says, that at Rochester, when the influenza of 1803 ceased, "an exanthematous fever prevailed, which did not appear to attack any except those whom the influenza spared." (Mem. of Med. Soc. vol. vi. p. 589.)

Dr. Gibney reports that "at Navan in Ireland, after the influenza of 1803, a low fever, almost constantly prevailing in that town, disappeared for a considerable time." (Med. and Phys. Journ. vol. x. p. 527.)

Dr. Currie says that "at Holywell, a populous town eighteen miles from Chester, and where there is a large cotton manufactory, a typhous fever of uncommon malignity had prevailed for a considerable time: the manufacturers and inhabitants of the town had not been free from it for more than two years. On the appearance of the influenza in the spring of 1803, the typhus entirely ceased, and only one case of fever has occurred since (nearly three months). I have not for many years known this country so healthy as since the influenza disappeared." (Ibid. p. 214.)

Dr. Rush remarks that, during the prevalence of the influenza at Philadelphia, he saw no sign of any other epidemic, and that the scarlatina anginosa, which prevailed during the summer, disappeared after the 1st of October, but appeared again after the influenza left the city. It blended itself with every species of chronic complaint." (Rush's Med. Inquiries, vol. ii.)

"The influenza was *the precursor* of the malignant yellow fever, which, commencing in the beginning of September, 1802, at Port Royal and St. Pierre's, Martinique, among the French seamen and soldiers lately arrived from France, committed the most frightful devastations amongst them." (Mem. of M. S. vol. vi. p. 599.)

"During the prevalence of influenza at Vienna, from December 1788 to May following, there were scarcely any instances of real pleurisies or peripneumonies, though these often appeared during that season in former years." (*Dr. Carenus*, Med. Comment. vol. xvi. p. 161.)

Dr. Chisholm mentions the exemption from the severe influenza of 1789 in its malignant form, *after a remarkable change in the weather*, of some estates in the island of Grenada, which had been attacked by it in its milder character *before the change took place.* (Med. Com. vol. xv.)

While the influenza of 1762 was in London, peripneumony and angina were unusually and almost universally prevalent in the country, (*Sir G. Baker*, de Cat. Epid. p. 18); and Dr. Carmichael Smyth relates, that "although the epidemical catarrh of 1782 quickly disappeared in the metropolis, it seemed to leave behind it an epidemical constitution which prevailed during the rest of the summer: and the fevers even in the end of August and beginning of September assumed a type resembling in many respects the fever accompanying the influenza." (Med. Com vol. i. p. 71.)

After the disease had continued some weeks, it was observed to change its character in several places. In Dublin Dr. Cleghorn remarked that the fever with which the influenza of 1782 was accompanied, became remittent, and sometimes intermittent; in London it was intermittent, at Stamford and the Isle of Man, "low and putrid." (Med. Com. vol. i. p. 25.)

We can scarcely look over the histories of influenza without perceiving a connection between this disease and morbid affections of the mucous surface of the stomach and intestines. Thus Huxham has recorded the frequent appearance of cholera and diarrhœa in July, September, and October, after the spring influenza of 1733. (De Aere, &c. vol. i. 86 and 88.) The same author describes the "dysenteria cruenta epidemica," which raged at Plymouth and the adjacent country, both before and after the influenza of 1743: and he adds that "he did not know whether the former disease might not be considered a translation of the latter to the intestines; but he had observed that *epidemic dysentery* was very rarely to be met with in the spring. (Ibid. ii. 99, 103.)

Sir George Baker follows up his account of the epidemic catarrh of 1762 in London with a description of the epidemic dysentery which imme-

diately succeeded it in that city, (Opus cit.); and both he and Dr. Reynolds remarked that in 1775 diarrhœa sometimes followed the attack of influenza. (Mem. of Fothergill, supra cit.)

Dr. Hamilton states that in the neighbourhood of Newcastle-upon-Tyne, "the influenza of 1782 was accompanied with colic pains and cramps in the region of the abdomen and stomach, and some had purging." (Mem. of Med. Soc. vol. ii. p. 435.)

In France, in the influenza of 1803, "gastric irritation was one of the most frequent complications of the disorder, and appeared in some measure to constitute an essential part of it." (Dict. des Sc. Méd. Art. *Grippe*, p. 362.)

Dr. Bertram of Hull remarked that some of the attacks of influenza in 1803 nearly resembled cholera-morbus, others cynanche tonsillaris; and he goes so far as to express "a firm conviction of the three diseases being different types of the same disorder, and occasioned by the same cause."—(Mem. of Med. Soc. vol. vi. p. 332.)

Diarrhœa seems to have preceded, as an epidemic, the influenza of 1803, at Plymouth Dock, as in 1743 and 1788; for Dr. May says that early in the year "diarrhœa and cholera were very prevalent; so nearly similar to that preceding the influenza of 1788, that to many of his friends he hazarded a pretty confident opinion of an expected return; and in this he was not deceived." (Med. and Phys. Journ. x. p. 291.)

It must be fresh in the recollection of most that the epidemic cholera which in a milder character appeared in many parts of Great Britain last year (1831), and is now running so fatal a career in its malignant type, was preceded by the influenza; and we know that the same herald of that formidable epidemic was seen also at Warsaw, Paris, and other places; and was lately announced even in the United States of America a short time before the cholera made its appearance in the transatlantic cities.

These facts are collected to show that there is a closer connection between some epidemic diseases, both as to their affinity and their causes, than we commonly imagine; and that it is only by a very enlarged view of their phenomena in different countries that we can hope to improve our knowledge in this obscure branch of science.

THOMAS HANCOCK.

INSANITY.—SECT. 1.—**Remarks on attempted definitions of Insanity.—Different varieties of the Disease referred to three principal Forms.**

Writers on insanity are generally agreed as to the difficulty of inventing a satisfactory definition of that disease. It is perhaps impossible to comprise in a few words a characteristic description of mental derangement which may prove to be of practical use; and it is not an easy matter to discover one that even includes all the essential features of the object which it is proposed to define. The latter of these requisites will be obtained if we describe insanity as consisting in "a disordered state of the functions of the brain, which gives rise to disturbances in the operations of the mind." This definition may correctly be applied to madness, but it also includes a variety of other diseases; and hence it becomes necessary to render the description more particular by exclusions and restrictions. It must be added, for example, that the disturbance in the mental operations ensuing from the morbid cause in the brain is not allied to coma or to loss of consciousness and sensibility, in order to exclude from the definition apoplexy and disorders of the same class. For a similar reason it has been common to observe that madness is a species of delirium distinct from that which is symptomatic of typhus and other febrile diseases. There are some other morbid states of the brain and of the faculties dependent for their exercise on the functions of that organ, which must in like manner be excluded by express limitations. Such are congenital idiotism, and the imbecility of old age. Now it is obvious that a definition loses all its utility when it is found necessary to encumber it with so many particular restrictions, and it is therefore better to give up the attempt to define insanity in general terms.

But the practical purpose of a definition, which is to give a clear and distinct conception of the thing to be described, will be secured if we can determine and classify the various disturbances which the mental operations undergo. These disturbances, however, present very different phenomena in different instances of the disease, and we cannot attempt to draw up a concise account of them until we have briefly noted their principal varieties.

It is generally supposed that the intellect or the reasoning faculty is principally disordered in persons labouring under mental derangement. Mr. Locke made a remark, that "madmen do not appear to have lost the faculty of reasoning; but having joined together some ideas very wrongly, they mistake them for truths, and they err as men do that argue right from wrong principles." From Mr. Lock's time it has been customary to observe that insane persons reason correctly from erroneous premises; and some instances of hallucination, or some particular erroneous impression, have been looked for as the characteristic of the disease, or an essential circumstance in it. Dr. Cullen seems to have had Mr. Locke's observation in his mind when he laid down the definition of madness which occurs in his First Lines. He describes this disease to be "in a person awake a false or mistaken judgment of those relations of things which, as occurring most frequently in life, are those about which the generality of men form the same judgment; and particularly when the judgment is very different from what the person himself had before usually formed." Cullen attempted to draw even this description within narrower limits, by observing that "there is generally some false perception of external objects, and that such false perception necessarily occasions a *delirium or erroneous judgment*, which is to be considered as *the disease*." That this is by far too limited an account of madness, and only comprises one, and that by no means the most frequent form of mental derangement, every person must be aware who has had opportunities of extensive observation.

Of those lunatics whose intellectual faculties are manifestly disordered, there is always a con-

siderable proportion in whose minds it is impossible to trace any particular hallucination or erroneous perception or recollection. The rapid succession of thoughts, the hurried and confused manner in which ideas crowd themselves into the mind in a state of incoherence, or without order and connection, is in very many instances among the most striking phenomena of madness. There are, likewise, cases of a different description, in which the intellectual faculties appear to have sustained but little injury, while the feelings and affections, the moral and active principles of the mind, are strangely perverted and depraved; the power of self-government is lost or greatly impaired; and the individual is found to be incapable, not of talking and reasoning upon any subject proposed to him, for this he will often do with great shrewdness and volubility, but of conducting himself with decency and propriety in the business of life. His wishes and inclinations, his attachments, his likings and dislikings, have all undergone a morbid change, and this change appears to be the originating cause, or to lie at the foundation of any disturbance which the understanding itself may have sustained, and even in some instances to form throughout the chief character or constituent feature of the disease. The older nosologists, Sauvages, Sagar, and Linnæus, were not wholly unaware of these distinctions; for in their distributions of mental diseases, we find (besides an order of *Vesaniæ* or *Hallucinationes*, in which erroneous impressions were supposed to affect the understanding) another department styled "*Morositates*" or "*Morbi Pathetici*," consisting of depraved appetites and other morbid changes in the feelings and propensities. The disorders, however, which are classed under these heads, are not, all of them at least, strictly forms of insanity; and Pinel appears to have been the first writer who, with a clear conception of the subject, distinguished a class of maniacal affections under the term of "madness without delirium or hallucination." Pinel, who was an acute and original observer, and whose opinions carry much weight on account of his extensive opportunities of investigating the history of madness, has made the following remark in reference to the sentiments of Mr. Locke. "We may justly admire," he says, "the writings of this philosopher, without admitting his authority upon subjects not necessarily connected with his inquiries. On resuming at the Bicêtre my researches into this disorder, I thought, with the above author, that it was inseparable from delirium," (meaning what is termed by English writers hallucination;) "and I was not a little surprised to find many maniacs who *at no period gave evidence of any lesion of the understanding*, but who were under the dominion of instinctive and abstract fury, as if the active faculties alone had sustained injury.

The examples given by Pinel in illustration of the above remark were not fortunately chosen, and they are all of one kind, namely, of that in which the principal phenomena of the disease were violent fits of anger or rage. The general observation which the author has so clearly enounced, that insanity consists, in certain cases, in a morbid perversion of the affections and moral feelings exclusively, and without any perceptible lesion of the intellectual faculties, is a fact of the highest importance pathologically and practically, and the opinion of Pinel in this particular deserves the most attentive consideration. It will be found that later practical writers, though they have not made the same statement in so decided a manner, have yet given a testimony which leads to the same result. The following remarks by M. Esquirol, who is less systematic than Pinel, prove that he was led to a similar conclusion by the strict observation of facts.

"The insane conceive an aversion for those persons who are most dear to them, revile them, illtreat them, anxiously shun them, in consequence of their mistrust, their suspicions, and their fears. Prejudiced against every thing, they are afraid of every thing. A few appear to form an exception to this general rule, in preserving a sort of affection for their relatives and friends; but this feeling of attachment, which is sometimes excessive, subsists without confidence in those persons who before the attack of the disease had been the directors of the thoughts and actions of the patient. A melancholic, who is devotedly attached to his wife, is deaf to her counsels and advice. A son would sacrifice his life for his father, but will not make the slightest attempt, in compliance with the entreaties of the latter, to overcome the morbid impression which occasions him so much grief."

"This moral alienation is so constant," says M. Esquirol, "that it appears to me to be the proper characteristic of mental derangement. There are madmen in whom it is difficult to discover any trace of hallucination, but there are none in whom the passions and moral affections are not disordered, perverted, or destroyed. I have in this particular met with no exceptions."

"A return to the proper and natural state of the moral affections," says the same writer, "the desire of seeing once more children or friends; the tears of sensibility; the wish manifested by the individual to open his heart and return into the bosom of his family, to resume his former habits, afford a certain indication of cure, while the contrary dispositions had been a mark of approaching insanity, or the symptom of a threatened relapse. This is not the case when there is merely a disappearance of the hallucination, which then only is a certain sign of convalescence, when the patients return to their natural and original affections." (*Esquirol*, Dict. des Sc. Méd., tom. xvi.)

If the opinion expressed by these writers is founded on real facts,—and that it is so the writer of the present article is well assured from ample proofs afforded by his own observation,—it must be evident that it leads to very important results. It will be necessary, in conformity with it, and with the varieties of phenomena which the disease really presents, to classify the different forms of madness or insanity under the following divisions.

1. Moral insanity, or madness consisting in a morbid perversion of the natural feelings, affections, inclinations, temper, habits, and moral dispositions, without any notable lesion of the intellect or knowing and reasoning faculties, and particularly without any maniacal hallucination.

2. Intellectual insanity, or madness attended with hallucination; in which the insane person is impressed with the belief of some unreal event as of a thing which has actually taken place, or in which he has taken up some notion repugnant to his own experience and to common sense, as if it were true and indisputable, and acts under the influence of this erroneous conviction.

3. There is another well-marked division of maniacal cases, in which the whole mind, if we may use the expression, seems to be equally deranged. The most striking phenomena in this form of the disease are the rapidity and disorder with which the ideas follow each other, almost without any discoverable connection or association, in a state of complete incoherence and confusion. It is impossible to fix the attention of the patient long enough to obtain a reply to the most simple question. His understanding is wholly lost in the constant hurry of ideas which crowd themselves upon him, and which appear to exceed the power of distinct utterance, while his habits betray a corresponding degree of restless activity and extravagance.

The most appropriate designation in our language for this species of disease is *incoherent madness*, a term given to it long ago by Dr. Arnold. It is named by Pinel *dementia* or *démence*, dementedness. Pinel has given an admirable definition of it: "Rapid succession, or uninterrupted alternation of insulated ideas, and evanescent and unconnected emotions; continually repeated acts of extravagance; complete forgetfulness of every previous state; diminished sensibility to external impressions; abolition of the faculty of judgment; perpetual activity."

If we are correct in assuming that all the varieties of mental derangement may find their place under one of the three descriptions we have thus marked out, a definition or short nosography of madness will be furnished by enumerating the characteristics of the three forms. We may then describe insanity as "a chronic disease manifested by deviations from the healthy and natural state of the mind; such deviations consisting either in a morbid perversion of the feelings, affections, and habits, or in disturbances of the intellectual faculties, under the influence of which the understanding becomes susceptible of hallucinations or erroneous impressions of a particular kind; or, thirdly, in a state of mental incoherence, or constant hurry and confusion of thoughts."

We shall now endeavour to trace an accurate description of the actual phenomena of insanity, containing the results of long and attentive observation. In discriminating the different varieties of the disease, we shall neither deviate further than is necessary from the arrangements of former writers, nor shall we follow in every respect the nosological divisions which they have adopted. The reader will, if we are not mistaken, find data in the following outline sufficient to confirm and illustrate the preceding remarks, and to show how far the distinctions we have endeavoured to establish are complete.

Sect. II. — Phenomena of Madness described.

1. *First Appearances of the Disease.*—The first appearances of madness are very different in the various forms of the disease and in different cases. Sometimes the complaint breaks out at once, without any previous indications; the manners of the patient are observed to be unusually impetuous; his conversation hurried; his mind full of projects, which he pursues with restless activity. He betrays the absolute derangement of his understanding by announcing some false and absurd impression, or by acting upon it. When his attempt is resisted, or when by accident he explains the motive which incited him, his condition is at once made evident, and the necessity of restraint becomes obvious. Such is the mode in which insanity makes its attack in the greater number of cases. In other instances the actual appearance of disturbance in the intellect is preceded by a period of uncertain duration, in which an unsound state of mind exists, but displays itself in a different manner. A certain waywardness or singularity of character, an unsteadiness in pursuits and inclinations, a fickleness or capriciousness of temper and habit, is observed for some time before the individual is set down by his relatives as a lunatic. This stage of the disease may last for years. M. Pinel mentions the case of a man who believed his wife to have been deranged only six months, at the commencement of which period she had sustained an attack of violent mania, but after repeated inquiries was at length convinced that she had not been in a sound state of mind for fifteen years. The same writer likewise observes that in many instances the origin of mental derangement has been referred, on tracing its history, to a period of four, ten, or even of fifteen or twenty years before the time when it became fully manifest, or when a disordered state, previously ambiguous, changed its character into that of ordinary or decided mania.

Cases of disease affecting the mind, such as we have described, and in which the succession of symptoms and the development of the complaint follow the order just pointed out,—a certain period either of melancholy dejection or of morbid excitement, attended with a disturbed and unnatural state of the feelings, temper, and habits, preceding, and after a time ushering in a clearly marked attack of insanity—are in fact only examples of a transition from one form or state of mental disorder to another, which is more strongly characterized and more easily distinguished. There are, however, numerous instances in which phenomena similar to those of the previous stage last for many years, perhaps during life, sometimes maintaining their ambiguous and undefined character, at others becoming aggravated in degree, but without undergoing a transition into the peculiar form of madness attended with marked disturbance of the intellectual faculties. Of this description are the cases of mental disease which we purpose to distinguish under the term of moral insanity.

First Form of the Disease.—Moral Insanity.—This form of mental disease has been said above to consist of a morbid perversion of the feelings, affections, habits, without any hallucination or erroneous conviction impressed upon the understanding; it sometimes coexists with an apparently unimpaired state of the intellectual faculties.

There are many individuals living at large, and not entirely separated from society, who are affected in a certain degree by this modification of insanity. They are reputed persons of singular, wayward, and eccentric character. An attentive observer may often recognise something remarkable in their manner of existence, which leads him to entertain doubts as to their entire sanity, and circumstances are sometimes discovered on inquiry which assist in determining his opinion. In many instances it is found that there is an hereditary tendency to madness in the family, or that several relatives of the person affected have laboured under other diseases of the brain. The individual himself is discovered in a former period of life to have sustained an attack of madness of a decided character. His temper and dispositions are found on inquiry to have undergone a change; to be not what they were previously to a certain time; he has become an altered man, and this difference has perhaps been noted from the period when he sustained some reverse of fortune, which deeply affected him, or since the loss of some beloved relative. In other instances the alteration in his character has ensued immediately on some severe shock which his bodily constitution has undergone. This has been either a disorder affecting the head, a slight attack of paralysis, a fit of epilepsy, or some fever or inflammatory disorder which has produced a perceptible change in the habitual state of the constitution. In some cases the alteration in temper and habits has been gradual and imperceptible, and it seems only to have consisted in an exaltation or increase of peculiarities which were always more or less natural or habitual.

In a state such as that above described, many persons have continued for years to be the sources of apprehension and solicitude to their friends and relatives. The latter in many instances cannot bring themselves to admit the real nature of the case. The individual follows the bent of his inclinations; he is continually engaging in new pursuits, and again relinquishing them without any other motive than mere caprice and fickleness. At length the total perversion of his affections, the dislike and even enmity manifested towards his dearest friends excite greater alarm. When it happens that the head of a family labours under this ambiguous modification of insanity, it is sometimes thought necessary from prudential motives, and to prevent absolute ruin from thoughtless and absurd extravagance, or from the result of wild projects and speculations, in the pursuit of which the individual has always a plausible reason to offer for his conduct, to make some attempt with the view of taking the management of his affairs out of his hands. The laws have made inadequate provision for such contingencies, and the project is often unsuccessful. If the matter is brought before a jury, and the individual gives pertinent replies to the questions that are put to him, and displays no particular hallucination,—a feature which is ordinarily looked upon as essential to madness,—it is most probable that the suit will be rejected.

Several practical writers have left a testimony, which is sufficiently conclusive, as to the existence of moral insanity, though they have not designedly and in set terms marked it as a distinct form of the disease.

We have already observed that M. Esquirol has stated his opinion to be, that moral alienation, or a perverted state of the affections, is, rather than intellectual aberration, the characteristic of mental derangement. M. Georget likewise describes the state we have alluded to as a particular modification of madness. He observes "that individuals predisposed to mental disease by a faulty education or by previous attacks, have often continued for a long time, or perhaps even during their whole lives, to attract observation by caprices in their deportment, by something eccentric in their manner and habits of life, by an ill-regulated fondness for pursuits of the fancy, and the mere productions of the imagination, combined with a striking inaptitude in the study of the exact sciences." The last-mentioned particular will scarcely be allowed to constitute a characteristic trait of madness in this country, whatever may be the case in France. "These persons are noted," continues the same writer, "for singularity of opinions, of conduct, for transitory fits of intelligence, or sallies of wit, which are too strongly contrasted with their habitual state of nullity or monotony; by a levity in thoughts, a weakness in judgment, a want of connection in their attempts at reasoning. Some individuals are presumptuous, desirous of undertaking every thing, and capable of applying themselves to nothing; others are extravagant and mobile in the utmost degree in their opinions and sentiments; many are susceptible, irritable, choleric, and passionate; some are governed by pride and haughtiness without bound; a few are subject to vague anxieties or to panic terrors."

It must be observed that, although M. Georget has described this state of disease as a first stage, or as the period of what he terms with M. Esquirol the *incubation* of madness, yet, as he says that it often lasts through the life of the individual, we may consider his testimony as given, in point of fact, in favour of the real existence of moral insanity as a particular modification of disease.

Individuals labouring under this disorder are capable of reasoning or supporting an argument on any subject within their sphere of knowledge that may be presented to them, and they often display great ingenuity in giving reasons for their eccentric conduct, and in accounting for and justifying the state of moral feeling under which they appear to exist. In one sense, indeed, their intellectual faculties may be termed unsound, but it is the same sense in which persons under the influence of strong passions may generally be said to have their judgment warped, and the sane or healthy exercise of their understandings impeded. They think and act under the influence of strongly excited feelings, and a person accounted sane is under such circumstances proverbially liable to error both in judgment and conduct.

We have already had occasion to observe that the existence of moral insanity as a distinct form of mental derangement has been recognised by Pinel. The following example recorded by that writer is a characteristic one:

"An only son of a weak and indulgent mother was encouraged in the gratification of every caprice and passion of which an untutored and violent temper was susceptible. The impetuosity of his disposition increased with his years. The money with which he was lavishly supplied removed every obstacle to the indulgence of his wild desires. Every instance of opposition or resistance roused him to acts of fury. He assaulted his adversary with the audacity of a savage; sought to reign by force, and was perpetually embroiled in disputes and quarrels. If a dog, a horse, or any other animal offended him, he instantly put it to death. If ever he went to a fête or any other public meeting, he was sure to excite such tumults and quarrels as terminated in actual pugilistic rencontres, and he generally left the scene with a bloody nose. This wayward youth, however, when unmoved by passions, possessed a perfectly sound judgment. When he became of age, he succeeded to the possession of an extensive domain. He proved himself fully competent to the management of his estate, as well as to the discharge of his relative duties, and he even distinguished himself by acts of beneficence and compassion. Wounds, law-suits, and pecuniary compensations were generally the consequences of his unhappy propensity to quarrel. But an act of notoriety put an end to his career of violence. Enraged with a woman who had used offensive language to him, he precipitated her into a well. Prosecution was commenced against him, and on the deposition of a great many witnesses, who gave evidence to his furious deportment, he was condemned to perpetual confinement in the Bicêtrice."

The morbid and irregular excitement of the active propensities, and the total want of self-control, which are so conspicuous in moral insanity, display themselves in various ways. Almost every passion or feeling of the mind gives in different cases the character to the disease when displayed under a certain modification, which it would not be easy to describe in accurate terms. Violent gusts of passion breaking out without cause, and leading to the danger or actual commission of serious injury to surrounding persons, are the features of disease in most of the cases mentioned by Pinel. These were examples of madness, consisting in intense irascibility without lesion of the understanding. There are other instances in which malignity has a deeper die. The individual, as if actually possessed by the demon of evil, is continually indulging enmity and plotting mischief, and even murder, against some unfortunate victim of his malice. When this is connected with the false belief of some personal injury actually sustained, the case does not fall under the head of moral insanity, simply so termed. It involves hallucination or erroneous conviction of the understanding. But when the morbid phenomena include merely the expressions of intense malevolence, excited without ground or provocation, actual or supposed, the case is strictly one of moral madness. And such instances are more frequent than it will be easy for many persons to believe.

Some maniacs display their condition by a propensity to commit every species of mischief, though devoid of any feeling of malevolence A case of this description, strongly marked, was lately pointed out to the writer of this article in the York Lunatic Asylum, by Dr. Wake, the able and intelligent physician to that institution. The individual is a youth of good temper, cheerful and active, having no defect of intellect whatever that could be discovered, even after long observation. He is continually prone to commit every kind of mischief in his power; and not long ago escaped from his confinement and made his way to Bishop-Thorpe Palace, with the design to set it on fire. Dr. Wake has given his assurance that several cases have occurred precisely similar to that above related in all essential symptoms, during his attendance at the asylum, which has continued seventeen years, and that he considers no point in the history of madness better established by facts than the existence of moral insanity, strictly and exclusively so termed, and in conformity with the definition above laid down.

A large number of cases falling into this division of diseases, are those in which a disposition to melancholy and dejection of mind exists, without any illusion of the understanding connected with it. A constant feeling of gloom and sadness clouds all the prospects of life: the individual, though surrounded with all the comforts of existence, and even, exclusively of his disease, suffering under no internal source of disquiet, at peace with himself, with his own conscience, with his God, yet becomes sorrowful and desponding. All things, present and future, are to his view involved in dreary and hopeless gloom. This tendency to morbid sorrow and melancholy, as it does not destroy the understanding, is often subject to control when it first arises, and probably receives a peculiar character from the previous mental state of the individual, from his education, and his religious or irreligious character. Persons of well-regulated minds, when thus affected, express grief and distress at the inaptitude of which they are conscious to go through the active duties of life: frequently they feel a horror of being driven to commit an act of suicide or some other dreadful crime. This idea haunts them, and renders them fearful of being a moment alone. It, however, subsides, and such cases often terminate in recovery. Persons of an opposite character give themselves up to *tædium vitæ*, to morose disgust; they loathe their very existence, and at length, unless prevented, put an end to it.

A propensity to theft is often a feature of moral insanity, and sometimes it is the leading if not the sole characteristic of the disease. The writer of this article has lately seen a lunatic, confined in an asylum, who would only eat when he had stolen food, and his keeper made it a constant practice to put into some corner within his reach various articles destined for his sustenance, in order that he might discover and take them furtively. Many instances are upon record of individuals noted for a propensity to steal, without the desire of subsequent possession, though in other respects of sound mind, or at least not generally looked upon as deranged. Probably some of these would afford, if accurately scrutinized, examples of moral insanity, whilst others might be found referable to eccentricity of character

The discrimination—if indeed the two things are essentially different—could only be made in particular instances by taking into the account a variety of circumstances, such as the hereditary history of the individual and his consanguinity with persons decidedly insane, his former character and habits, and the inquiry whether he has undergone a change in these respects at some particular period of his life.

This form of insanity has been, if we are not mistaken, in many instances the real source of moral phenomena of an anomalous and unusual kind, and of certain perversions of natural inclination which excite the greatest disgust and even abhorrence.

In some instances moral insanity displays itself in a want of self-government, in a continual excitement, and unusual expression of feeling, or in thoughtless and extravagant conduct. A female, modest and circumspect, becomes violent and abrupt in her manners, loquacious, impetuous, talks loudly and abusively against her relations and guardians, before perfect strangers. Sometimes she uses indecent expressions, and betrays without reserve unbecoming feelings and trains of thought. Not unfrequently persons affected with this form of disease become drunkards; they have an uncontrollable desire for intoxicating liquors, and a debauch is followed by a period of raving madness, during which it becomes absolutely necessary to keep them in confinement. Individuals are occasionally seen in lunatic asylums who under such circumstances have been placed under control. After the raving fit has passed off, they demand their release; and when they obtain it, at the first opportunity resort to their former excesses, though perfectly aware of the consequences which await them.

A form of mental disease has been described by some writers, which, though not of frequent occurrence, is occasionally seen, and is well known to those who have extensive means of observation. It is peculiar to old age, and has been termed *delirium senile*, and by Dr. Burrows, who has accurately distinguished it, senile insanity. It constitutes a variety of moral insanity.

This disordered state makes its appearance in old men who have never before been insane or suspected of any tendency to mental derangement. It consists, like other forms of moral insanity, in a morbid excitement of passions and a remarkable perversion of the temper and propensities. The whole moral character of the person is changed. "The pious," says Dr. Burrows, "become impious, the content and happy discontented and miserable, the prudent and economical imprudent and ridiculously profuse, the liberal penurious, the sober drunken." In some elderly persons, impulses which had long been effete become of a sudden excited, and a strong tendency to vicious habits is displayed. "In fact, the reverence which age and the conduct suited to it always command, is converted into shame and pity at the perversion of those moral and social qualities which, perhaps, have hitherto adorned the patient's declining days." This description coincides accurately with the character of moral insanity. There are instances, though rare, of the appearance of hallucinative madness in old persons, but the case we have now described is of a different character, and consists in a disordered condition of the moral or active powers alone.

The following cases will afford some observations illustrative of the history of moral insanity.

J. K—, a farmer, several of whose relatives had been the subjects of mental derangement, was a man of sober and domestic habits, and frugal and steady in his conduct, until about his forty-fifth year, when his disposition appeared to have become suddenly changed in a manner which excited the surprise of his friends and neighbours, and occasional grief and vexation in his family. He became wild, excitable, thoughtless, full of schemes and absurd projects. He would set out and make long journeys into distant parts of the country to purchase cattle and farming-stock, of which he had no means of disposing; he bought a number of carriages, hired an expensive house ready furnished, which had been inhabited by a person much above his rank, and was unsuitable to his condition; he was irascible and impetuous, quarrelled with his neighbours, and committed an assault upon the clergyman of the parish, for which he was indicted and bound to take his trial. At length his wife became convinced that he was mad, and made application for his confinement in a lunatic asylum, which was consequently effected. The medical practitioners who examined him were convinced of his insanity by comparing his late wild habits and unaccountable conduct with the former tenor of his life, taking into consideration the tendency to disease which was known to prevail in his family. The change in his character alone had produced a full conviction of his madness in his friends and relatives. When questioned as to the motives which had induced him to some of his late proceedings, he gave clear and distinct replies, and assigned with great ingenuity some plausible reason for almost every part of his conduct. After a period of time passed in great seclusion, his mind became gradually tranquillized; the morbid excitement of his temper and feelings disappeared; he was set at liberty, and has since conducted himself with propriety.

A brother of the above patient has been at two different times confined in the same asylum, labouring under symptoms of derangement in all essential particulars resembling those above detailed. His disorder has consisted chiefly in morbid excitement, wildness and irregularity of conduct, differing from his usual habits and character, without any hallucination or disturbance of the intellectual faculties. He has on both occasions remained in the asylum until he was fully convalescent, and after his departure has acknowledged his conviction that he had been deranged, and in a state requiring control and seclusion from society.

Abraham B——, a working tradesman, of industrious habits, conducted himself with propriety until about forty-six years of age, and had accumulated a considerable property from the fruits of his exertions. About that period he lost his wife, and after her death became more and more penurious. At length he denied himself the comforts, and in a great measure even the necessaries of life, and became half-starved and diseased his

body was emaciated and beset with scaly eruptions. Mr. S——, a gentleman who had long known him, hearing of the condition into which he had sunk, sent a medical practitioner to visit him, by whose advice B—— was removed from a miserable dirty lodging to a lunatic asylum. Mr. S——, who was present on the occasion, observed that Abraham B——, previously to his quitting the room in which he had immured himself, kept his eyes fixed on an old trunk in the corner of the apartment. This was afterwards emptied of its contents, and in it were found, in the midst of various articles, dirty bank-notes, which had been thrown into it apparently at different times, to the value of more than a thousand pounds. Abraham B——, after his removal to an asylum, where he had wholesome food and exercise, soon began to recover from his bodily infirmities, and at length became anxious to be at large. The writer of this article visited him, and conversed with him for some time, in order to ascertain his mental condition. He betrayed no sign of intellectual delusion, nor did it appear that any thing of that description had ever been a part of his complaint. His replies to questions were rational according to the extent of his natural capacity. He was determined to go and manage his property, and get a wife who should take care of him. In a few days after his release he was married to a servant belonging to the lunatic asylum where he had been confined. His new wife found after some months that it was impossible to endure the strange conduct of her husband, and after trying various experiments, brought him back to the asylum, with a certificate from a medical man, who had examined him and declared him to be insane. He still remains in confinement, and his derangement is now more complete than formerly, as it plainly involves his intellect. He now raves against his wife, declares that she is married to her own brother, vows bitter revenge for the injuries he has sustained, and vehemently demands his release whenever he is visited by the inspecting magistrates.

Abraham B——'s case was at first merely a perversion of moral habits. If the real nature of this case was otherwise in any degree doubtful, it is rendered obvious by the more decided madness which has since appeared. Very clear indications of a disturbed intellect appeared in his manners and expressions soon after the commencement of his second confinement.

It is probable that many instances of extreme avarice and penury, as those of Elwes and Dancer, and other celebrated misers, were in reality cases of disease. Whether such individuals were proper objects for confinement is quite another question. In the case of Abraham B—— the interference of others was necessary in order to preserve his existence.

The cases above detailed resemble each other in many particulars, and especially in the circumstance that the morbid perversion of habits which characterized each of them took its rise without any cause that could be distinctly traced. In the following instance the appearance of analogous derangement was preceded and probably caused by constitutional disease, and by the suppression of a long-continued and habitual discharge from the lungs.

The case we are about to relate is a tolerably characteristic example of moral insanity. During one period of its course, when aggravated by temporary circumstances, it indicated some tendency to assume the form of monomania. The patient displayed a proneness to suspicion, and to entertain unfounded impressions connected with the motives and characters of individuals. But these impressions never became deeply fixed or took a permanent hold of the mind, and they soon disappeared. For some years both previously and subsequently to the period alluded to, the complaint wore that appearance which has, we trust, been correctly designated under the term prefixed to the present section.

The account of this case is but slightly abridged from a narrative drawn up by a near relative of the patient.

A. M—— is a maiden lady, aged about 48, of short stature, and somewhat deformed; her natural disposition was steady and industrious. She accomplished her undertakings by dint of application rather than by energetic or sudden efforts. She was constant rather than ardent in her attachments, free from resentment, never the subject of lively emotions; a great respecter of truth, just and very exact in all that she said or did. Her charitable acts were commensurate with her means, deliberate, and the result of principle rather than arising from the mere impulse of compassionate feeling. She was cautious and reserved in her communications, and scarcely if ever formed any familiar and particular intimacies with young persons of her own sex. Being debarred by her infirmities from associating with the young and active, she seemed more like an adult member of the family than a child. She was very clever in arithmetic and in all matters of business, and was fond of regulating and controlling the little affairs of those who formed the domestic circle surrounding her. Young persons and servants, finding that they derived advantage from her advice, generally gave her an opportunity of gratifying her inclination. Her dress, which was always plain and in good taste, was to her an object of greater attention than it often is to persons of fashion.

In March 1822 she was attacked by severe inflammation in the lungs, attended by expectoration of bloody mucus. This was the first time in her life when it was necessary to confine her to bed. She submitted with great reluctance to the restrictions that were needful for her recovery, and would not be persuaded until she had heard the opinion of an old friend of her family, who is a medical practitioner, that the means adopted were proper and required by her case. She was then, however, in a great measure reconciled, and after seven or eight weeks was so far recovered as to bear a removal into her native county. At this period nobody believed that she would survive another winter. Her restoration to her usual state of health was very slow, and her sister, who was her constant companion, perceived with sorrow that her temper was now much changed. She appeared restless, always wishing to go somewhere, or to do something to which she was unequal; becoming unjustly irritated when she could not urge her sister, whose health and spirits were

declining, to fall in with her ideas, and occasionally giving way to reproaches which were keenly felt. She tried every method of persuasion to induce her sister to go to the neighbourhood of London, though for the preservation of her life the latter had been obliged to give up the custom of spending the winter there, and the attempt was considered dangerous to her. Every inducement, every argument was suggested to promote this favourite object: other towns were too warm and too cold, too hilly, too much intersected with water, too *foggy*. In 1827 she determined to go without her sister to H———, near London. She went, and from her letters her sister perceived that she was living in a state of excitement far surpassing that of her former habits; paying short visits to friends in the surrounding villages, going out in the common short stages, without so much regard to weather as was usual to her even in the summer; receiving small parties at home, attending a very crowded church, writing a great many letters, &c. &c. She used to write to her sister in rather a boastful style, frequently mentioning her good health and high spirits, as if to justify her choice of a residence near the metropolis. When the sisters met during the summer at their house in ——shire, her high spirits were gone, she looked more aged than the time elapsed would have led any one to expect, took less interest in her garden, appeared exhausted, and, without contributing her share to the conversation, used frequently to sleep in her chair. She lay much in bed, nursed herself up, and in October went again to H——, as much agog as ever. Another winter passed much as the preceding one had done. She spoke much again of her high spirits, visited much, was observed to be unusually liberal in her presents to most of her acquaintances. A second summer of inertness was succeeded by a winter at H——. She was now weak, indisposed for visiting, and, in fact, so much worse as to be unable to follow her inclinations. In the spring of 1830 she had an attack of the same nature as that in 1822, but not so severe or lasting. In the summer she was nearly as before, and quite as eager to resume her plans, as enthusiastic in her commendations of every body and every thing at H——.

About this time some riots took place in London, and more were apprehended. She now expressed herself as apprehensive that "very awful times were at hand," wrote frequent letters to her sister full of indecision, and expressive of distrust in her servants, her host and his family. A friend who called upon her "was shocked to find her in so low a way." He thought her unfit to be alone, and she was unwilling to adopt any plan for leaving her lodgings, or having any one with her. She said she should be happy with her sister, and knew that she should be taken care of by the latter, but dreaded becoming a burden to her and making her ill; yet feared that if she did not go to her sister, "some one would put her where no one would know, and cause her to sign papers which she ought not to sign." She was evidently apprehensive of being sent to a lunatic asylum. She thought her host was a writer of "*Swing letters*,"* and dreaded that he might fill the house with combustibles, and blow it up with her in it. A medical man who was taken to see her, said that she was in a state of great mental excitement, and ought to be taken to her sister as soon as possible. The frost was severe when she was escorted to her sister, who was then settled at Bristol, yet she took no cold, experienced no injury from fatigue, and lost that feeling of terror to which she had for some time been subject. Since she has been with her sister, she has been increasingly obstinate, suspicious, undecided, restless, parsimonious even to meanness, indisposed to any employment, bodily or mental, except as far as relates to a most troublesome interference with the most minute actions of others. Could she have her own way, she would control the food, dress, and employment of every one near her. She has become negligent in dress, and comparatively dirty in her habits, yet has an insatiable desire for new clothes, which she never finds the right time to wear. She is constantly predicting her utter ruin, is sure she will not have money enough to live until such and such a time; knows that enough will not be found to pay Dr. ——; knows he will not let any one of so shabby an appearance be long in his house; does not know where she shall go when he is tired of her; thinks that "it is the devil that makes her behave as she does;" "that her heart is hardened to do what she ought not to do;" "she is like the man spoken of in the Gospel, who could not be bound even with fetters." She sees people look at her; hopes they don't think she drinks too much; is quite sure she never did. These impressions are continually varying; but no sooner is her mind tranquillized on one subject than another source of disquietude arises, so that she exhausts every person who is long with her. Her bodily health is better than it was for years previous to her mental derangement. A constitutional asthma, to which she has been subject from the age of six or seven years, has nearly subsided, and the habitual profuse expectoration has considerably diminished. She wears less clothing, and appears less sensible to cold or damp than heretofore.

The writer of this article has had several interviews with the subject of the foregoing relation, during some of which she gave replies to a variety of questions referring to the past and actual state of her health, both bodily and mental. No impression could be traced in her mind that bore the character of maniacal hallucination. The circumstance most observable in her condition was a perpetual disposition to find fault with every action, even the most trivial, that was witnessed by her. When asked if she was not aware of this propensity, she seemed to give an unwilling affirmative to the question, and she was plainly aware of the fact, for on the inquiry being made whether the habit had only existed of late years, or had been a part of her natural character, she steadily averred that such was not her natural disposition, "that she was formerly very different."

The preceding cases present no great difficulty as to the conclusion to be adopted respecting the nature of the disorder; such, at least, was the

* It may hereafter require to be explained that, about the period above mentioned, the threatening letters of incendiaries in various parts of the country frequently bore the signature of *Swing*.

opinion of all the medical practitioners who examined personally the individuals. We now proceed to mention an instance of moral peculiarity which will not allow of so decided an opinion.

Miss A. N—— is a maiden lady of very singular aspect and manners. She has for many years estranged herself from nearly all the friends of her family, formerly a large circle, and associates almost exclusively with her domestics, and one relative who lives with her. Her chief amusement and delight is to invent and relate the most unfounded, and sometimes the most absurd and ridiculous stories. Sometimes she has displayed mortification when in danger of being detected in the invention of these falsehoods, or when questioned respecting them. Her expression of countenance is sometimes very wild and peculiar. She has never shown any decided mark of mental derangement, nor is she considered as insane, though it has frequently been observed by those who have known her, "that they should not at any time be surprised to hear of her being mad."

No person would venture to pronounce this lady to be insane, or at least to found any proceeding upon the opinion; and yet it is highly probable that her eccentricity depends upon constitutional peculiarity. One of her parents was decidedly insane during a considerable period of life, and the other, as well as several ancestors and relations by blood, laboured under diseases of the brain, of which fatuity in different degrees was the result.

It is generally admitted that there are few questions which physicians are called upon to decide, of more difficult determination than that which relates to the existence or non-existence of insanity in examples which present no obvious and clearly discoverable disturbance in the state of the intellectual faculties. It may be apprehended that the perplexities with which this subject has been environed, will rather be increased than diminished by the recognition of a form of mental derangement admitting the designation here adopted. But the real facts of a difficult question must be known and described in their true relations, before a solution can be sought with any prospect of advantage; and if we are not mistaken in the view of this subject and the facts connected with it, which we have adopted, it will be found that something is gained by admitting a position which places the inquiry relative to the existence of insanity in a different light from that in which it has most frequently been regarded.

Those who are interested in studying the relations of this disease will do well to consult the able and well-known work of Dr. Conolly. The question how far persons labouring under merely moral insanity are incapacitated for sustaining the relations of society, belongs to medical jurisprudence.

3. *Second Form of Insanity. Madness attended with Hallucination.*—We now proceed to varieties of disease which are of far more easy discrimination than that species of madness which involves merely a perversion of the moral affections and habits. When the patient is found to labour under a disturbed condition of the understanding, when a morbid delusion or hallucination is impressed upon his mind, no doubt can be entertained as to the actual existence of insanity. By the term *hallucination* we mean to express what Cullen and Pinel denote by that of delirium, viz. a belief of unreal events or relations, apprehended under the influence of disease to be actual and real, or some notion repugnant to common sense, impressed upon the mind as true and indisputable, the patient acting under the influence of his erroneous conviction.

There are two very different states of disease attended with this symptom. In one the understanding is, when exercised on many subjects, comparatively clear, and the morbid impressions are partial; in the other, the disturbed condition of the intellectual faculties involves all the operations of the mind. These states are respectively termed monomania, and mania or ordinary mania. Each of them requires a separate consideration.

Of Monomania.—Cases of partial insanity have been by former writers distinguished by the term melancholia, and it has been supposed that a majority of them are of the description by which that term was suggested, involving gloomy impressions and dejection of mind: the designation of mania has been at the same time applied to raving madness, or insanity accompanied by violent excitement. This distinction is laid down in the most explicit terms by Van Swieten. "A maniâ distinguiter melancholia, quod nondum adsit sævus ille furor, qui in maniacis observatur. Præterea et illud signum diagnosticum melancholiæ est, quod uni et eidem cogitationi pertinacissime inhæreant tales ægri, et fere circa hanc illamve opinionem delirant tantum; in reliquis omnibus sanam ostendunt mentem et sæpe acutissimum ingenium." It was well observed by M. Esquirol, that the distinction connected with this appropriation of terms is not uniformly supported by facts, as the impressions of partial madness are not always of a gloomy character: the mind, in this form of disease, is not in every instance abandoned to sorrow and melancholy. The term monomania, meaning madness affecting one train of thought, or involving only a single morbid impression, was on these considerations substituted. and has generally been adopted of late times instead of melancholia.

The notion, however, which many persons entertain as to the nature of the disease thus designated, is very far from being in general correct. It is supposed that the mind is perfectly sound when its faculties are exercised on any subject unconnected with a particular impression which constitutes the entire disease. Cases are on record which, if faithfully recorded, fully come up to this description. In general the real character of monomania is very different. The feelings and affections are in that state which has been described under the head of moral insanity, and on this it would appear that some hallucination or maniacal delusion has supervened. The following case will serve to illustrate the observation which we have just made.

Mr. E. W——, a gentleman about thirty years of age, has laboured for several years under symptoms of moral insanity. He has been long dejected in spirits and morose in temper, dissatisfied with himself, and suspicious of all that surrounded him. He was capricious and unsteady in his pursuits, frequently engaging in some new study

in the most sanguine manner and soon abandoning it in despair of making any progress, though possessed of good talents and considerable acquirements of knowledge. He passed the requisite period of time at one of the Universities, but could not be prevailed upon to go in for his degree, either through timidity and want of resolution, or, as it was conjectured by his friends, from a morbid apprehension that the examiners would not deal fairly with him and award him the station to which he aspired and believed himself entitled. He applied himself afterwards to the study of medicine, and then to that of metaphysics, and speedily relinquished both. He frequently changed his residence, but soon began to fancy himself the object of dislike to every person in the house of which he became the inmate. His peculiarities appearing to increase, he was visited by two physicians, who were desired to investigate the nature of his case. On being questioned narrowly as to the ground of the persuasion expressed by him, that he was disliked by the family with which he then resided, he replied that he heard whispers uttered in distant apartments of the house indicative of malevolence and abhorrence. An observation was made to him that it was impossible for sounds so uttered to be heard by him. He then asked if the sense of hearing could not, by some physical change in the organ, be occasionally so increased in intensity as to become capable of affording distinct perception at an unusual distance, as the eyes of mariners are well known to be accommodated by long effort to very distant vision. This was the only instance of what might be termed hallucination discovered in the case after a minute scrutiny. It seemed to be a late suggestion. The individual had been for years labouring under a gradually increasing moral insanity. His judgment had become at length perverted by the intensity of his morbid feelings, and admitted as real an erroneous impression, suggested by his fancy, which happened to be in harmony with his feelings, and served to account for them.

There are, indeed, cases of insanity attended with hallucination on a constant erroneous impression, in which this system will appear to many persons to afford but little evidence as to the real nature of the complaint. The delusive impression appears to be so blended with the prevalent disorder of the feelings and affections, or it seems to be so much the result of the peculiar circumstances by which the patient is surrounded, that it is scarcely contemplated as a distinct and peculiar phenomenon. These remarks will receive illustration from the following case.

Mr. H. P—— had been for many years confined in a lunatic asylum, when, an estate having devolved upon him by inheritance, it became necessary to subject him anew to an investigation. He was examined by several physicians, who were unanimous in the opinion that he was a lunatic; but a jury considered him to be of sound understanding, attributing his peculiarities to eccentricity, and he was consequently set at liberty.

The conduct of this individual was the most eccentric that can be imagined: he scarcely performed any action in the same manner as other men; and some of his habits, in which he obstinately persisted, were singularly filthy and disgusting. For every peculiar custom he had a quaint and often ludicrous reason to allege, which indicated a strange mixture of shrewdness and absurdity. It might have been barely possible to attribute all these peculiarities, as well as the morbid state of temper and affections, to singularity in natural character and to the peculiar circumstances under which this person had been placed. But there was one conviction deeply fixed on his mind, which, though it likewise might be explained by the circumstances of his previous history, seemed to constitute an instance of maniacal delusion. Whenever any person whom he understood to be a physician attempted to feel his pulse, he recoiled with an expression of horror, and exclaimed, "If you were to feel my pulse, you would be lord paramount over me for the rest of my life." The result has proved that confinement is not always necessary in cases of this description. Mr. H. P—— has remained at liberty for many years, and his conduct, though extremely singular, has been without injury to himself or others.

We shall conclude our observations on this subject by the record of a remarkable case which illustrates the tendency of moral insanity to degenerate into, or ultimately assume, the character of monomania. The individual who was the subject successively of these forms of disease, was for several years in a state which gave rise to apprehension in many of his friends, while some who narrowly observed him were fully convinced of his insanity. The disease at length broke out in a form which admitted of no doubt.

A gentleman remarkable for the warmth of his affections, and the amiable simplicity of his character, possessed of great intellectual capacity, strong powers of reasoning, and a lively imagination, married a lady of high mental endowments, and who was long well known in the literary world. He was devotedly attached to her, but entertained the greatest jealousy lest the world should suppose that, in consequence of her talents, she exercised an undue influence over his judgment, or dictated his compositions. He accordingly set out with a determination of never consulting her, or yielding to her influence, and was always careful, when engaged in writing, that she should be ignorant of the subject which occupied his thoughts. His wife has been often heard to lament that want of sympathy and union of mind which is so desirable in married life. This peculiarity, however, in the husband so much increased, that in after years the most trifling proposition on her part was canvassed and discussed by every kind of argument. In the meantime he acquired strange peculiarities of habits. His love of order, or placing things in what he considered order or regularity, was remarkable. He was continually putting chairs, &c. in their places; and if articles of ladies' work or books were left upon a table, he would take an opportunity *unobserved* of putting them in order, generally spreading the work smooth, and putting the other articles in rows. He would steal into rooms belonging to other persons for the purpose of arranging the various articles. So much time did he consum

in trifles, placing and replacing, and running from one room to another, that he was rarely dressed by dinner-time, and often apologised for dining in his dressing-gown, when it was well known that he had done nothing the whole morning but dress. And he would often take a walk in a winter's evening with a lanthorn, because he had not been able to get ready earlier in the day. He would run up and down the garden a certain number of times, rinsing his mouth with water, and spitting alternately on one side and then on the other, in regular succession. He employed a good deal of time in rolling up little pieces of writing-paper, which he used for cleaning his nose. In short, his peculiarities were innumerable, but he concealed them as much as possible from the observation of his wife, whom he knew to be vexed at his habits, and to whom he always behaved with the most respectful and affectionate attention, although she could not influence him in the slightest degree. He would, however, occasionally break through these habits; as on Sundays, though he rose early for the purpose, he was always ready to perform service at a chapel a mile and a half distant from his house. It was a mystery to his intimate friends when and how he prepared these services. It did not at all surprise those who were best acquainted with his peculiarities, to hear that in a short time he became notoriously insane. He fancied his wife's affections were alienated from him, continually affirming that it was quite impossible she could have any regard for a person who had rendered himself so contemptible. He committed several acts of violence, argued vehemently in favour of suicide, and was shortly afterwards found drowned in a canal near his house. It must not be omitted that this individual derived a predisposition to madness by hereditary transmission: his father had been insane.

Of Mania.—The phenomena of mania in its ordinary form are very distinguishable from those of monomania. The aspect, the voice, the gestures of the lunatic in the active state of maniacal derangement, form a contrast with the retired and morose habits of the sullen monomoniac. In cases, however, of mania, distinctly so termed, one impression often occupies the mind of the individual for the time being, and this is frequently some hallucination respecting his own person, some magnific dream of self-importance and superiority. M. Pinel says, "I was frequently followed at the Bicêtre by a general, who said that he had just been fighting an important battle, and had left fifty thousand men dead on the field. At my side was a monarch who talked of nothing but his subjects and his provinces. In another place was the prophet Mahomet in person, denouncing vengeance in the name of the Almighty. A little further was a sovereign of the universe, who could with a breath annihilate the earth. Many of them seemed to be occupied by a multiplicity of objects, which were present to their imaginations. They gesticulated, declaimed, and vociferated incessantly, without appearing to see or hear anything that passed. Others, under illusive influence, saw objects in forms and colours which they did not really possess. Under the influence of an illusion of that kind, was a maniac who mistook for a legion of devils every assemblage of people that he saw. Another maniac tore his clothes to tatters, and scattered the straw on which he lay, under the apprehension that they were heaps of twisted serpents."

Ordinary mania, or madness affecting the mind with a general disturbance of the intellectual faculties, is sometimes preceded by occasional fits of excitement and confusion, in which the understanding is hurried and disordered. But it differs from monomania in making its attacks for the most part suddenly and without any premonitory symptoms. An individual, after having undergone an unusual degree of mental and bodily exertion and fatigue, after a fit of intoxication, which in this country is one of the most ordinary of exciting causes of madness, after the excitement of violent passions or anxieties, after exposure to cold and the inclemencies of weather, passes sometimes a day or two in a state of feverish disorder and general uneasiness, and two or three restless nights. His mind is then found to be confused; he appears scarcely to know what he says, talks nonsense, repeats his words frequently, expresses his feelings with an absurd degree of warmth and enthusiasm, cries, laughs, utters rapid and confused sentences in a hurried and impetuous manner. "In the course of a few days, or sometimes at first, he is seized with violent agitations, expresses vague and continual apprehensions, is subject to fits of terror; he is in a state of constant excitement and sleeplessness; he indicates the troubled state of his mind by unusual gestures, by singular appearances of the countenance, and by actions which cannot fail to strike in a forcible manner every observer. The various aspects which the symptoms of the disease assume at this period, have never been more graphically described than by M. Pinel. "The patient sometimes keeps his head elevated and his looks fixed on high; he speaks in a low voice, or utters cries and vociferations without any apparent motive; he walks to and fro, and sometimes arrests his steps as if excited by the sentiment of admiration, or wrapt up in profound reverie. Some insane persons display wild excesses of merriment, with immoderate bursts of laughter. Sometimes, also, as if nature delighted in contrasts, gloom and taciturnity prevail, with involuntary showers of tears, or the anguish of deep sorrow, with all the external signs of acute mental suffering. In certain cases a sudden reddening of the eyes and excessive loquacity give presage of a speedy explosion of violent madness, and the urgent necessity of a strict seclusion. One lunatic, after long intervals of calmness, spoke at first with volubility, he uttered frequent shouts of laughter, and then shed a torrent of tears; experience had taught the necessity of shutting him up immediately, for his paroxysms were at such times of the greatest violence. It is often observed that extatic visions in the night are the preludes to fits of maniacal devotion; and by enchanting dreams, or by the fancied apparition of a beloved object, it sometimes happens that erotic madness breaks out with violence, when it may either assume the character of a calm reverie, or display nothing but extreme confusion in the ideas and the entire subversion of reason."

When the disease has taken a firm hold on its

unfortunate victim, it sometimes gives rise to all the internal effects, and displays all the external phenomena which the most intense feelings of human misery, resulting from the real calamities of life, may be imagined to produce. The maniac who becomes the subject of violent excitement "is seen in a state of extreme agitation, with his face flushed, his eyelids inflamed, and his eyes sparkling, his temples beating violently; he talks, cries, sings, grieves, gets into fits of rage by night and by day, and is incapable of taking rest. The melancholic, also, in extreme agitation, but wrapt up in himself, goes to seek in some quiet and dark recess a refuge from his panic terrors, from his gloomy and despairing thoughts; or the means of putting into execution his baneful designs. The insensible and stupid, incapable of anything, remain unconscious of surrounding objects, and do not even exert themselves to satisfy their most urgent wants. At this period of madness there is a constant want of sleep: the patient often experiences a feeling of tension and of heat in the head, without, however, complaining of it. Sensibility to external impressions, as well as to all bodily changes, is so much lessened, that blisters, cauteries as well as exposure to intense cold, will sometimes produce but little expression of pain or distress.

4. *Of Incoherent Madness.*—A very peculiar and well characterized form of mental derangement is that of incoherent madness, or incoherency, in which the mind is occupied by a rapid succession of unconnected thoughts and evanescent emotions, and becomes entirely incapable of reflection, or even of distinct apprehension. Such cases are frequent, and are to be met with in every receptacle containing a considerable number of lunatics. Incoherent madness, or incoherency, is the most proper designation for this state of disease, as it describes the essential and characteristic feature. By Pinel the term *démence*, or dementia, has been adopted; and to this there would be no objection if it were not for the circumstance that the same term has been used by Esquirol and Georget with a different meaning, and that confusion would hence arise from an ambiguous designation. Under the term *démence*, the writers last mentioned describe that state approaching to fatuity or idiotism, which is the termination of protracted insanity, and in this sense the word is now commonly received. Since this is a morbid condition very distinguishable from that incoherency which is a primary and idiopathic form of mental derangement, each of these states of disease must have a particular epithet.

This form of madness is in some instances a primary affection; at least the tendency to incoherency displays itself very early in the progress of the case. The disease commences with great excitement; the patient is restless and unusually active; his manners are full of bustle and violence; his countenance flushed; he has sleepless nights; his thoughts follow each other with turbid rapidity; and his whole appearance strongly resembles that of a man of excitable temperament intoxicated with wine or spirituous liquors. In many cases there is no hallucination or erroneous impression on the mind that can be traced, but the violent and irrational activity of the patient is such as to require coercion. The succession of confused and imperfect ideas becomes after a time so rapid as to preclude distinct utterance. The association which connects images in the mind seems to be lost, or at least cannot be traced, and the thoughts appear to be single and insulated. Words and sentences are half pronounced; the voluntary movements are without design, and the effort to perform them is incomplete; it is impossible to fix the attention of the patient sufficiently for obtaining a reply to the shortest question; he becomes almost insensible to the existence of external objects, talks incessantly, or repeats the same word or half sentence over to himself; he takes his food, when it is offered to him, by hasty snatches, and swallows it greedily, or spits it out again in order to continue his unmeaning jargon. After this state of excitement has continued for some time, it gradually subsides, and the discase either continues with mitigated violence, but still with the same form of incoherency and want of connection in the course of thoughts and feelings, or the expressions gradually appear to be more connected, the patient becomes capable of sleep, and a slow progress towards the restoration of the reasoning faculty is perceptible. The writer of the present article has witnessed several instances of complete recovery of the mental powers after the existence, during many weeks and even months, of maniacal phenomena answering to the above description; and every physician who has had opportunities of inspecting lunatic asylums must have observed many cases in which the state of incoherency has terminated in recovery, and others in which it has become chronic and permanent.

The following case described by Pinel is a well marked instance of the morbid state now under consideration, and it will be sufficient to prove that the affection termed by that writer *démence* is precisely what we have designated as incoherent madness.

"An ardent but ill-informed patriot, and one of the warmest partisans of the celebrated Danton, was present at the sitting of the legislative body, when the writ of accusation was pronounced against that deputy. He withdrew in consternation and despair, shut himself up in his own apartment for several days, and surrendered himself to the influence of the most gloomy ideas. 'What! Danton a traitor!' he repeated without ceasing; 'then is there no man to be trusted; the republic is lost!' His appetite and sleep forsook him. Complete insanity ensued. Having undergone the usual treatment at the ci-devant Hôtel Dieu, he was removed to the Bicêtre. He passed several months in the infirmary of this hospital in a state of tranquil reverie, uttering incessantly half-expressed and unconnected sentences. He talked alternately of daggers, sabres, dismasted vessels, green meadows, his wife, his hat. He never thought of eating but when food was actually put into his mouth; and in respect to his functions he was almost levelled with an automaton."

The chronic form of incoherence presents similar phenomena, but in a milder degree. Patients in this last state have intervals of rest; they sleep, and have periods of tranquillity during their waking hours, but seldom or never display coherence and arrangement in their ideas, or make any approach towards a sane and vigorous use

of the reasoning powers. Neither have they any appearance of melancholy or abstraction, but they are capable of being momentarily excited by objects which impress their senses and by the scenes around them, though their impressions are transitory and evanescent. They talk to themselves or to others for a long time in phrases scarcely connected by any perceptible link, and in which there is rarely a glimpse of meaning; and if any association can be traced in their thoughts, it is of the most trivial kind, and depending on a word or some sensible object which for a moment attracts their attention. They will sometimes repeat the same word or half sentence many times, but soon forget it.

The disease which we have now described under the designation of incoherent insanity has been by some writers identified with dementia, or the first stage of fatuity. It is, however, a particular form of mental disease, assuming its peculiar character from the first, and displaying phenomena very different from those of dementia, though, like other forms of madness, it is liable, when long protracted, to pass eventually into fatuity. The writer of this article has seen in private practice and in hospitals several well-marked cases of incoherent madness in the acute form, which ran their course and terminated in recovery without passing into the chronic stage. Of the chronic form, which approaches most nearly to dementia, but may yet be distinguished from that state of disease in its ordinary appearances, some illustrative cases have been pointed out to him in the Lunatic Asylum at Fishponds, near Bristol, by Dr. Bompas, the humane and intelligent conductor of that establishment. Two of these occur in brothers, whose symptoms are very similar, though those of one are more strongly marked than of the other. Although the former of these individuals has been in confinement for many years, his countenance does not display the well-marked aspect of dementia, of which M. Esquirol has given so excellent a delineation. If questioned, he replies with an intelligent look, but in words quite beside the subject, and chatters about a hundred unconnected things in the course of a few minutes. If you repeat the question, it only increases his volubility without apparently drawing his attention a whit more nearly to the subject of inquiry.

5. *Observations on the State of the Faculties in Madness.*—It has been a question frequently agitated among medical writers, in what precise changes in the organic operations of the brain, as well as in the mental processes which result from these operations, madness consists. The present is not a suitable opportunity for entering into a full discussion of this subject. In a practical point of view, all that is requisite will be obtained by a brief inquiry into the actual condition of the intellectual faculties in insane persons.

It may be observed that consciousness generally remains unimpaired in lunatics, though its exercise, in some cases of madness with hallucination, is connected with singular phenomena. The patient is conscious of his sensations, but he sometimes expresses himself as if his notion of personal identity were strangely confused. He talks and reasons about his feelings as if they were those of another individual. These are by no means frequent cases, and in general lunatics have a distinct perception of their personal identity, and refer their sensations and ideas correctly to themselves.

Sensation likewise remains unimpaired in the insane: the organs of sense at least are not the seats of disease, nor are those processes in the nervous structure on which sensation depends in a deranged state. The sensations produced by light and sound are sometimes morbidly acute, from temporary affection of the organs of sight and hearing; but this is accidental, and by no means a circumstance characteristic of madness. The effects of cold and other painful impressions are in some instances disregarded by lunatics, but this seems to be merely a result of intense excitement of the mind and its direction to other feelings and operations. Such cases are not so frequent as they are supposed to be, and in general lunatics are sensitive of external impressions.

Perception of external objects is generally unimpaired, but in some cases it is strangely affected and perverted by the morbid impressions on the mind, and by the influence of the prevailing hallucinations.

Maniacal hallucinations are of two kinds. Dr. Cullen has remarked that "*there is sometimes a false perception* or imagination of things present that are not; but this is not a constant nor even a frequent attendant of the disease. The false judgment is of relations long before laid up in the memory." This means that the hallucination seldom refers to the scene actually present, but to the impressions of memory. When, however, the maniacal reverie becomes very intense, it produces hallucinations or false impressions which represent unreal objects as actually present. Even in this case it does not appear that perception is impaired. Some particular phantasms, the creations of reverie, are presented to the mind in colours so vivid as to produce an effect similar to that of actual perception; the patient in other respects makes no mistakes with regard to place or time; his perceptions of external objects are correct and uniform whenever his attention is directed to perceptible things; but he is so intent upon his reverie, that for the most part he totally neglects them; his fancy becomes so intense in its operation as to carry him away from the influence of his external perceptions, and to environ him with visions of unreal scenes.

We have often seen a lunatic under this form of disease walk up and down a frequented place, sufficiently alive to external objects to avoid falling in the way of horses and carriages, or running against foot-passengers, but so intent upon the scene presented by his excited imagination as to be busily employed in issuing commands to troops of which he imagined himself to be the general, and in directing them to enfilade to the right and left, and perform a variety of evolutions. All this he performed with a voice and gesture that were perfectly natural and consistent with reality. To this modification of madness belong those maniacal hallucinations termed by some writers idilomania or dæmonomania, in which the lunatic fancies that he sees and holds converse with imaginary beings. The conception of the mind is so vivid and intense that it withdraws consciousness

entirely from the sensations excited by surrounding objects, which nevertheless exist, and occasionally under particular circumstances give rise to perception. Maniacal hallucinations have, however, a much firmer hold on the belief in some cases of madness than the strongest evidence afforded by perception, and hence the futility of those projects which are occasionally suggested for surprising lunatics into a conviction of their false judgments. An insane female confined in an asylum had a firm persuasion that her husband was dead. When he came to visit her, she asserted that it was the devil who had assumed his form. Her recollection and perception had remained unimpaired, but the insane hallucinations overcame their evidence and held possession of her mind.

The power of reasoning or judgment does not appear to be so much impaired in madness as the disposition to exercise it on certain subjects. Often there is a manifest unwillingness to admit any evidence unfavourable to the false notions impressed upon the mind, while great ingenuity is displayed in finding arguments which may tend to make it apparently more reasonable. A case illustrative of this remark has been already mentioned.

In many instances of madness it would appear that the characteristic feature of the disease is a morbid inclination to indulge in reverie, and to yield the judgment and all the faculties to its control. The impressions of reverie are so modified by disease as no longer to be distinguishable from those of memory or active reflection. We may venture to say that this observation will go far towards explaining the mental phenomena of the disease.

6. *Disorders in the state of the physical functions attendant upon madness.*—The phenomena of madness which attract most observation, and which indeed characterize the disease, are those which depend upon the disordered state of the cerebral functions; but other processes in the living body are likewise in a state of derangement. There is in most cases of insanity, besides the morbid condition of the brain and nervous system, more or less of disturbance in the physical functions; the secretions, excretions, appetite, and digestive processes are frequently disordered. Medical writers have differed in opinion as to the relation which these affections bear to the cause of insanity.—Pinel has stated it to be the result of his inquiries that the primary seat of mental alienation is generally in the region of the stomach and intestines, and that from that centre it propagates itself, as it were, by irradiation, and deranges the understanding. Others have looked upon the disorders in the functions of the viscera as merely contingent results of a primary disease, seated in or immediately affecting the brain.

Whichever of these opinions may be correct, the general, or at least the frequent co-existence of disorder in the physical functions with that affection of the brain from which the deranged state of the mind immediately results is an indisputable fact.

The physical functions are differently affected in different forms of madness. In disorders of slow and gradual accession, and especially in those cases in which the mind is melancholy and depressed, a torpid state of the vital and natural functions for the most part prevails; the circulation is languid; the pulse weak and generally slow; the extremities cold; the skin cold and clammy; most of the secretions are defective; the bowels are torpid and sometimes obstinately constipated and flatulent, requiring strong doses of aperient medicine. The appetite is defective; digestion is impaired; sometimes there is a constant loathing of food, which, if the patient were not obliged to eat, would induce him to starve himself, and it is often extremely difficult to persuade persons in this state to swallow nutriment sufficient for the preservation of life. Emaciation and loss of strength inevitably result from these circumstances, but they are sometimes not so striking as any person would anticipate.

Attacks of maniacal disease, which break out suddenly with great excitement of the passions, with general disturbance of the intellectual faculties, or with incoherence, are almost always accompanied by symptoms of fever or pyrexia more or less acute. The pulse is rapid, often full, and beating with disproportioned strength in the carotid and temporal arteries; the skin is hot and the tongue white; there is thirst, with loss of appetite, headach, sleeplessness, and great irritability; the secretions are deficient, the urine is high-coloured and scanty, and the bowels are constipated. The face is often flushed; the eyes are glossy and suffused; the conjunctiva is injected with blood, and the pupils are contracted. The patient sometimes complains of pain in the forehead and temples, with a sense of weight upon the head, or of constriction, as if the scalp were tightly drawn. It has been observed that in some instances persons who had previously suffered severely from headach have ceased to complain of it when madness has supervened, and that it has returned when such patients have become convalescent. Want of rest is often a troublesome and distressing symptom. Many patients pass whole nights without closing their eyes, or when they obtain sleep, it is short and agitated. In other instances a few hours of sound sleep are the prelude to a paroxysm of renewed excitement, the maniacal symptoms breaking out on waking with increased violence.

All the symptoms which refer themselves in a perceptible manner to the head are liable to undergo occasional exacerbations during the continuance of madness. Increased heat of the scalp, redness of the eyes, fulness and strong pulsation of the carotid and temporal arteries, want of sleep and consequent irritability of the temper and feelings, indicate and precede or accompany renewed periods of violence in the symptoms of mental derangement.

In many instances of maniacal disease there is much disturbance in the functions of the intestinal canal. This observation has been made more particularly in persons whose general health has been previously much neglected; in the inmates of some lunatic asylums; in individuals of the lower class, who have been subjected to hardships and unwholesome diet, as well as to cold and a

damp unwholesome atmosphere; in cases in which the disease has followed excesses of various kinds, or confinement on ship-board, with the use of salt provisions. In many instances of this description it has been found that the bowels had been long in a confined and torpid state. In those instances in which it is stated that the bowels are open and even more loose than natural, it often appears on further examination that a long-continued torpor and constipation have given way to diarrhœa; the abdomen, which had previously been swelled with indurated matter, has become more distended than before, flatulence being added to the load of solid contents but partially discharged. The evacuations are thin and watery, or contain mucus mixed with vitiated bile and recent aliment in an undigested state. Sharp and transient pains are experienced in various parts of the abdomen, which is often tender on pressure; at length, in very neglected cases, dysentery supervenes and brings on extreme emaciation. The tongue is often red or covered with a brown fur, and the mouth and fauces with a viscid mucus, which, together with saliva, the patient spits out in all directions. There is great thirst and a peculiar fetor of the breath, which extends to the whole person. The appetite is depraved; in many cases the patient has an aversion to all food; in other instances he has a keen and voracious desire for it, and greedily devours without selection every thing eatable that falls in his way. The skin is cold; there is a remarkable coldness of the extremities, resulting from the damp state of the skin and a want of energy in the circulation through the extreme vessels. In some cases of long duration, there are papular or scaly eruptions; and in exhausted and debilitated subjects, furunculi appear in various parts of the body which are much disposed to slough.

[See an interesting case, by Dr. Prichard, of the connection of insanity with tuberculous formations and ulceration in the intestinal canal, in *Provinc. Med. Journal*, Jan. 27th, 1844, or in *Amer. Journal of the Med. Sciences*, April, 1844, p. 445.]

Cases of madness, coming on with some degree of rapidity, are often preceded and sometimes accompanied or followed by suppressions of natural or customary discharges, by the disappearance of external diseases, or the cure or suspension of internal complaints. The relation which these changes bear to madness as causes or results may be different in different cases; they are connected circumstances of that disease. The catamenia, if not suppressed previously to the manifestation of cerebral disorder, soon become scanty, or cease entirely after its actual appearance. Lochiæ and other analogous effluxes are suppressed; ulcers, which had become habitual and had long discharged, are dried up; chronic eruptions generally disappear, or are materially lessened; symptoms of pulmonary phthisis in various stages cease or become mitigated in a remarkable degree. On the decline of maniacal disease, it is often found that the return of such discharges, or the revival of suspended trains of morbid symptoms such as we have described, is the harbinger of restoration to a sound state of mind, though not to complete bodily health.

Sect. III.—Of the Duration of Insanity, and of the Modes of its Termination.

The duration of insanity is various, and admits of no general estimate. In some instances this disease has subsided in the course of a few days after its commencement; in others it continues for many years. M. Esquirol has remarked that it is not uncommon to meet with inmates of lunatic asylums who have been twenty, thirty, or even forty years in confinement. The same observations must have occurred to every person who has been in the habit of visiting such establishments.

Insanity has three different terminations:—first, in recovery; secondly, in a state of fatuity, or of chronic and permanent failure or obliteration of the mental faculties; thirdly, in death. The last is generally the contingent result of some of those disorders in the physical functions of the body to which the insane are especially liable. We shall allot a separate consideration to the circumstances connected with each of these events of insanity.

1. *Of Recoveries from Insanity.*—Recovery from madness sometimes takes place suddenly, but more frequently it is gradual, and preceded by several periods of mitigation in the intensity of disease, and often by lucid intervals.

The prospect of recovery is much greater in young persons than in those of advanced years, and it diminishes, other circumstances being equal, with the patient's age. M. Esquirol has observed that few lunatics are cured after the sixtieth year. It must, however, be taken into the account that few comparatively are for the first time attacked by madness after that period of life.

The curability of madness, or, to speak more correctly, the proportion of maniacal cases which terminate in recovery, is likewise subject to great variation from circumstances which refer to the nature of the disease, its occasional complication with other maladies, the sex and constitution of the patient, the mode of treatment to which he is subjected, and the causes which have given rise to his disorder; and hence any general calculations on this subject are matters rather of curiosity than of practical value. One remark, however, may be of use, as it may encourage medical practitioners in their efforts to remove or mitigate the disease. Of cases which present no peculiarly unfavourable combinations, a much larger proportion terminate in recovery than is generally supposed, or than any person could be led to believe from the inspection of reports from hospitals. In these reports it generally happens that a great number of inveterate cases, and of such as are incurable from their conjunction with other diseases dangerous to life, and indicating changes in the organic condition of the brain, are blended with those of simple insanity in the general averages.

M. Esquirol has endeavoured, by comparing the reports of several extensive hospitals in France and England, to throw some light on the curability of madness, or on the proportion of recoveries. The following table presents some facts which are of great interest.

TABLE OF RECOVERIES FROM MADNESS.

		Admissions.	Recoveries.
In England.			
In Bethlem Hospital	from 1748 to 1794	8874	2557
" "	in 1813	422	204
In St. Luke's	from 1751 to 1801	6458	2811
In York Asylum		599	286
In the Retreat, near York	from 1801 to 1814	163	60
	Totals	16516	5918
In France.			
Charenton	from Nov. 22, 1798 to 1800, 22 July	97	33
	1803	499	161
Salpêtrière	from 1801 to 1805	1002	407
"	from 1804 to 1813	2005	1218
"	from 1806 to 1807	531	286
"	from 1812 to 1814	891	413
In M. Esquirol's private establishment	from 1801 to 1813	335	173
	Totals	5360	2691

From the data contained in this table, M. Esquirol concludes, "first, that the absolute number of recoveries from madness is about one in three; secondly, that the number of recoveries varies from one in four to one in two, or to one-half of the number of persons affected: this difference depends upon particular circumstances of locality, on the nature of the cases, and of the treatment pursued: thirdly, that cures are more numerous in France than in England." He adds that they are much more rare in Germany and in Prussia.

A much more extensive collection of reports from various lunatic asylums, both public and private, in England, France, and other countries, has been made by Dr. Burrows, who has constructed from these materials a table exhibiting the proportion of recoveries. The evidence afforded by such collections is very much confused, and in many instances rendered wholly inconclusive from the variety which exists in the regulation of different establishments as to the nature of the cases admissible into them, and the time during which the patients admitted are kept. For instance, the hospitals of Bethlem and St. Luke impose certain exclusions elsewhere unknown. They reject all patients who have been more than twelve months insane; those affected by paralysis, however slight, and by epilepsy or convulsive fits; idiots, the aged and infirm; those discharged uncured from other hospitals: there are likewise other exclusions besides those above mentioned, and all persons who have not recovered at the expiration of one year are dismissed. Yet on comparing the reports of these hospitals with those of other institutions, the regulations of which are less favourable to a high proportion of cures, and where no selection or exclusion exists, we do not find, as Dr. Burrows remarks, the relative number of recoveries to be so great as might be expected. It is indeed surprising to find that the reports of Bethlem Hospital, of a century and a half ago, give a greater proportion of cures than those of many years preceding 1817, when an improvement took place in the arrangements of that establishment. Dr. Burrows remarks on the authority of Stow, who derived his information from Dr. Tyson, physician to Bethlem Hospital, that "from 1684 to 1703, 1294 patients were admitted, of whom 890 were cured, which is a proportion of two in three. But from 1784 to 1794, 1664 patients were admitted, of whom 574, or rather more than one in three, recovered." It is probable that there were circumstances in the former arrangements which, if they were known, would explain this difference. On the whole, the results of Dr. Burrows' inquiries are much more favourable to British hospitals than those of M. Esquirol. It appears, indeed, from his statements that the proportions of recoveries in England are greater than those obtained in France, Germany, and, *à fortiori*, in any other country in Europe. This may be in some degree judged of by comparing the following statements, taken during late years, with those previously given from M. Esquirol's collections.

In Stafford Asylum, from 1818 to 1828, admissions 1000; cured 429; or about 43 in 100.

In Lancaster County Asylum, from 1817 to 1825, admissions 812; cured 322; or about 39 in 100.

In Wakefield County Asylum for the West Riding of Yorkshire, from 1819 to 1826, admissions 917; cured 384; or about 42 in 100.

[The experience of the insane institutions of the United States has been highly encouraging. They are admirably conducted institutions; yet it is not easy to deduce from them, or from the European institutions more than an approximation to the number of cures. Annual reports are certainly not well adapted to convey very positive information as to relative curability; and this is sufficiently shown by the discrepancy amongst them;—those which publish the smallest number of cases cured being by no means the least successful. The published ratio of cures is generally, indeed, higher than it ought to be, owing to the time being too short to enable an accurate judgment to be formed, and the patients being too often withdrawn or dismissed from the institution before they were wholly restored. Dr. Pliny Earle (*Amer. Journal of the Med. Sciences*, April 1843, p. 347) has drawn up the following table, which applies, in the case of all the institutions but one, to a series of years. In the Bloomingdale Asylum, New York, many cases of delirium tremens are received, which may account for the greater proportion of recoveries among males;—as a general rule, the greater number of restorations appearing to occur in the other sex.

ASYLUMS.	TIME.	MEN.			WOMEN.		
		Admitted.	Cured.	Per Cent.	Admitted.	Cured.	Per Cent.
Hanwell	1831 to 1840	1013	223	20.01	1016	226	22.24
Pennsylvania Hospital	1841	103	15	14.56	73	15	20.54
Bloomingdale	1821 to 1841	1692	848	50.12	906	352	38.91
Massachusetts State Hospital	1833 to 1841	680	365	53.67	637	392	61.53
Total		3488	1451	35.09	2632	985	35.80

(See, also, Dr. Woodward, in Eleventh *Annual Report of the State Lunatic Asylum, at Worcester, Mass.*, p. 39, Boston, 1844.)]

From these statements it clearly appears that M. Esquirol's computation of recoveries is much below what really takes place under favourable circumstances. The results are so different under different circumstances, that no general average can be of much value in a practical point of view.

Another inquiry, which admits of a more satisfactory elucidation, and which leads to results very interesting in their relation to prognosis, refers to the period of the disease during which recovery is chiefly to be expected. Some facts, tending to illustrate this question, were contained in a memoir presented by M. Pinel to the French Institute in 1800. It appeared from this memoir that the greatest number of recoveries from madness take place in the first month of its duration, the recoveries during the first being compared with those of succeeding months. The mean time for the duration of the disease, in cases terminating favourably, was fixed in the same document at from five to six months. This result was deduced from a selection of cases from which the author excluded all those which had been under previous treatment, as well as cases of long duration. A longer term is assigned to this disease, in cases terminating in recovery, by Mr. Tuke in his account of the Retreat at York; and M. Esquirol, whose accuracy of research in subjects of this nature gives to his authority the highest value, confirms the opinion of Mr. Tuke. He has drawn this conclusion from a statement of the cases admitted into the Salpêtrière during ten years, as shown by the following table.

TABLE OF RECOVERIES AT THE SALPÊTRIÈRE DURING TEN YEARS.

Admissions.	1804.	1805.	1806.	1807.	1808.	1809.	1810.	1811.	1812.	1813.	1814.	Totals of Cures.
209	64	47	7	4	3	2		1	1			129
212	73	54	4	2	2	1				1		137
206	78	49	10	3	1	1	1					143
204	60	55	11	1		2						129
188	64	57	4	2	1					2		130
209	48	64	9	4	1	3						129
190	48	51	7	1	3							110
163	44	30	8	3								85
208	75	41	11									127
216	50	49										99
2005												1218

It seems that the report on which this table was founded, extended from the year 1804 to 1813; 2804 female lunatics were admitted during this interval, of whom 795 were considered as incurable, on account of their advanced age, or because they were idiotic, epileptic, or paralytic subjects. The remaining 2005 were put under treatment without regard to the duration or peculiar character of their disease. Out of this number, 604 were cured during the first year, 497 in the second, 86 in the third, and 41 in the seven succeeding years. From these data M. Esquirol draws the following conclusions; first, that the greatest number of recoveries are obtained in the two first years; secondly, that the mean duration of cases that are cured is somewhat short of one year; thirdly, that after the third year the probability of cure is scarcely more than one in thirty. There are, nevertheless, examples which prove that we ought never to despair of the recovery of lunatics. M. Pinel, from Baumes, cites the case of a lady who passed twenty-five years in a state of lunacy, within the knowledge of the whole country where she lived, and who suddenly recovered her reason. "I have seen," says the same writer, "a girl who from the age of ten years was in a state of dementia, with suppression of the catamenia. One day, on rising from bed, she ran and embraced her mother, exclaiming, 'Mamma! I am well!' The catamenia had just flowed spontaneously, and her reason was immediately restored. Such facts are rare, but they serve to prove that from the duration of the disease alone there is no reason to despair altogether of recovery." [See the work of M. Esquirol, *Des Maladies Mentales* Paris, 1838.] A few instances of the same kind have occurred in several lunatic houses or public hospitals, from the superintendents of which the writer of this article has obtained information respecting them.

From another table published by M. Esquirol, it appears that, out of 269 maniacal patients, 27 were cured in the first month of their illness, 34 in the second, 18 in the third, 30 in the fourth, 24 in the fifth, 20 in the sixth, 20 in the seventh, 19 in the eighth, 12 in the ninth, 13 in the tenth, 23 after the first year, and 18 after two years. This is perhaps an attempt at a greater degree of accuracy in calculation than is, from the nature of circumstances, attainable. The same writer has made a remark in illustration of the greater

proportion of recoveries observed in the early period of madness, which is worthy of attention. He says, "I have constantly observed that in the course of the first month from the commencement of the disease a very marked remission takes place. About that period the maniacal excitement, which had previously run its course as an acute disorder, seems to have reached its termination as such, and it is then that it passes into a chronic state, the crisis having been incomplete. This remission, which I have watched with the greatest accuracy, must be attributed to the complaints which are complicated with madness at its commencement." The author implies, though he does not clearly express himself, that the natural termination of the disease, when unimpeded by complication with other maladies, or by more or less of organic lesion in the brain, is in the very early stage.

[It is exceedingly important to bear in mind the immense difference in the curability of insanity in recent and in chronic cases, which has been observed in other institutions besides those cited. In two "*Appeals to the People of Pennsylvania on the subject of a State Asylum for the Insane Poor*," which the writer prepared as Chairman of a Committee, the results in various insane establishments of this country were brought together. In one, the ratio of recoveries of those in whom the insanity was of less than 12 months' duration, was stated to be 82½ per cent.; whilst of the old cases it was only 15½ per cent. At the York West Riding Asylum, of 318 cases that had existed, according to Sir William Ellis, (*A Treatise on the Nature, Symptoms, Causes, and Treatment of Insanity*, Lond. 1838,) from one to thirty years, only 26 were cured; and of 173 old cases in the Bloomingdale Asylum, New York, in 1835, only 16 were restored.

Few patients who are more than 60 years old when attacked—it would seem from the experience of M. Esquirol—recover; and the result of the greater part of inquiries would appear to show, that restoration is most frequent in youth, and less so as age increases. Dr. Woodward, however, affirms, that in the Massachusetts State Hospital, at Worcester, persons attacked with insanity after forty years of age, recover in much greater proportion than those attacked before that age.]

Recoveries from madness are in many instances complete. There are numerous persons who have been insane for six or twelve months, or during a longer period, and have afterwards entirely recovered the vigour of their intellectual faculties, so as to be capable of as great and effective mental exertions as previously to the attack. Others, and perhaps these are the majority, are curable only to a certain point. These persons remain, as M. Esquirol has observed, in such a state of susceptibility that the slightest causes give rise to relapses, and they only preserve their sanity by continuing to live in a house where no mental agitation or inquietude, no unfortunate contingency is likely to fall to their lot, and throw them back into their former state. There are other individuals whose faculties have sustained such a shock that they are never capable of returning to the sphere which they had held in society. They are perfectly rational, but have not sufficient mental capacity to become again military officers, to conduct commercial affairs, or to fulfil the duties belonging to their appointments. Such cases may be about one-tenth in the number of recoveries.

Convalescents are as subject to relapse as those who are advancing towards recovery from other diseases. But lunatics are in many instances likewise prone to a recurrence of the disease after it has been entirely removed, or at least after its manifestations have long ceased to be observed. The same observation may be applied to other disorders of the nervous system. It would seem that one attack of disease has in these cases left the patient with a stronger predisposition than he formerly had to the complaint, whatever it may have been, and that the morbid tendency is strengthened after every renewed incursion. The most trifling circumstances have in these instances sufficient influence to produce the morbid condition of the brain and of the mind. At length the patient is scarcely ever in a lucid state; the intervals lessen in duration, and become more and more imperfect in degree, until disease finally becomes in a great measure permanent.

The proportion of cases in which madness is recurrent has been overrated. According to M. Pinel, in 71 cases out of 444 recoveries, relapse took place, or, rather, the disease was in those instances recurrent. This gives somewhat less than one-sixth of the whole number as recurrent; but the same writer allowed that out of the 71 cases 20 patients had previously relapsed, or had undergone several attacks, 16 had left the hospital at too early a period, 10 came afterwards under treatment and recovered without relapse, 14 had given themselves up to grief and intemperance, and several others were under circumstances unfavourable to continuance in health. M. Esquirol published a report of 2804 recoveries, in which number only 292 recoveries of disease took place, that is, a little more than one-tenth. M. Desportes, however, has stated that, in 1821, 52 recurrent cases were recognised at the Bicêtre, out of 311 admissions, that is, about 17 in a hundred; at the Salpêtrière in 454 admissions there were 66 relapses, about 15 in a hundred, or one-seventh. But in the proportion of recurrent cases indicated by this last report, it is probable that there were, as M. Georget has well observed, many cases which had been discharged in a state of incomplete recovery, as well as a considerable number of drunkards, who come habitually every year to spend a few weeks in the Bicêtre or the Salpêtrière, having been picked up in the streets in a state of intoxication.

In all instances we may consider it as certain that the improbability of recurrence increases with the length of the interval of time during which the patient has existed without manifesting signs of renewed disease, and that it is also greater in proportion to the completeness of the recovery. When the energy of mind is fully restored, relapse is much less to be feared than when it remains weak and excitable.

Second Termination—Fatuity—Dementia—Amentia.— The ultimate tendency of madness when protracted, and the state to which insane persons, if they do not recover, are in general sooner or later reduced, is that of fatuity. The fatuity which constitutes the last stage of mental derangement differs in its phenomena from con-

genital idiotism. It has more resemblance to the imbecility of extreme old age, but from this last affection, which we shall describe at the conclusion of the present treatise, it is distinguishable and in many instances very different. For the sake of greater precision we shall divide maniacal fatuity into two grades or stages. The first is that state which Esquirol and Georget have named *démence* or dementia, a term which is established by the authority of these writers, and has been received into general use; the second stage of fatuity, which is the last period of mental decay, and presents an almost entire obliteration of the faculties, may be properly distinguished by the term *amentia.*

1. *Dementia.*—The approach of dementation, or the first period of fatuity, is indicated by a comparative state of calmness succeeding to the previous excitement of the maniacal period. It is not the calmness of returning reason, but the result of mental activity worn out, the subsidence or obliteration of the affections or moral feelings, and the decay even of physical sensibility. It has been well remarked by M. Georget that the characteristic of dementation is a forgetfulness of the past, with a total indifference as to the present and future. Demented persons are generally quiet and inactive; they take little notice of persons or external things, without appearing to be occupied by any internal emotion or train of thought. They often, however, smile or laugh without any apparent reason, or sing, or pronounce, as if accidentally, single words or sentences. Some remain for days or weeks without uttering a word, or betraying by look or gesture the least consciousness of external impressions. Such impressions, however, are sometimes afterwards discovered to have been not entirely unobserved. Many appear, by their looks or replies to questions, to know and remember their friends or relatives, but scarcely display signs of emotion or sensibility on being visited by them. Not a few even in this state are capable of being employed in mechanical occupations. Females knit or sew, or perform any work with their hands to which they have been previously habituated; and men draw, or write letters or sentences, in which, however, their imbecility is generally conspicuous. Some patients have occasional periods of greater excitement, in which the symptoms of a more active state of madness resume their prevalence. In other instances mere physical activity displays itself at intervals in peculiar ways, as by running, jumping, or walking round continually in a circle or determinate figure.

The physical health of patients thus affected is in general tolerably good; they are often fat, have good appetites, digest their food, sleep well, and if in the previous stages of the disease they had been emaciated, they often recover their natural degree of plumpness on the approach of dementia. Hence the return of physical health without a corresponding improvement in the state of the mental faculties, is, as it has been remarked by the writer last cited, an unfavourable prognostic in cases of maniacal disease.

There are, however, some rare cases of recovery from this first stage of fatuity. Pinel informs us that many, especially young persons, who had remained in the Bicêtre several years or months in a state of absolute idiotism, have been attacked by a paroxysm of acute mania of twenty, or five-and-twenty, or thirty days' continuance. "Such paroxysms," he adds, "apparently from a reaction of the system, are in many instances succeeded by perfect rationality." The same result has been observed on the restoration of demented persons or of maniacs in the advanced stage of insanity after severe attacks of fever of that kind which is usually attended with delirium. Such attacks are often fatal to lunatics; but of those who recover them not a few are subsequently restored to the possession of their faculties.

These instances of restoration from fatuity take place only after the first stage. When the disease has passed into complete amentia, it is altogether hopeless.

2. *Amentia.*—Scarcely any exhibition of human suffering can be more deeply affecting than the aspect of a group of lunatics reduced to the last stage of fatuity, and those who have never witnessed such a spectacle can hardly imagine so abject a state of mental degradation. In a group of this description an individual may be seen always standing erect and immovable, with his head and neck bent almost at right angles to his trunk, his eyes fixed upon the ground, never turning them round, or appearing by any movement or gesture to be conscious of external impressions or even of his own existence. Another sits on a rocking-chair, which she agitates to and fro, and throws her limbs into the most uncouth positions, at the same time chanting or yelling a dissonant song, only capable of expressing a total inanity of ideas and feelings. Many sit constantly still, with their chins resting on their breasts, their eyes and mouth half open, unconscious of hunger or thirst, and almost destitute of the feelings which belong to merely physical life; they would never lie down or rise were they not placed in bed and again raised by their attendants. A great proportion of the patients who are reduced to this degree of fatuity are found to have lost the use of their limbs in a greater or less degree by partial or general paralysis.

From such a state it is scarcely imaginable that recovery ever took place, but patients in the last stage of fatuity often linger for many years. Their state, however, is not always uniform: some of them have comparatively lucid intervals, at which nature seems to make an effort to light up the mind and recall lost impressions and ideas. A patient has often been observed by the writer of this article, who sits all day in a wooden elbowed chair, with his chin hanging over his breast, appearing hardly conscious of existence and unable to assist himself in the calls of nature, who would not eat if food were not actually put into his mouth. He has been for several years in the same state, except that he occasionally appears to rouse himself, and for a short time to recover an unusual degree of animation. At such periods he will sometimes read a chapter in the Bible with a clear voice and a distinct and intelligible articulation.

3. *Of the termination of madness in Death.*—Madness is not to be reckoned among the diseases which are very dangerous to life. The state of the brain on which it depends, though incompatible with the continuance in a sound state of those functions on which the mental operations are as-

sociated, is yet such as to carry on other proccsses, dependent on the brain, which are subservient to physical existence.

This conclusion is established in a most convincing manner by the duration of insanity, and the cases even of longevity which occur among lunatics. We are informed by M. Desportes that among the lunatics at the Bicêtre in the beginning of the year 1822, one had been lodged there fifty-six years, 3 upwards of forty years, 21 more than thirty ycars, 50 upwards of twenty years, 157 more than ten years. At the Salpêtrière the entry of paticnts dated, 7 cases from fifty to fifty-seven years, 11 from fifty to sixty, 17 from forty to fifty.

The morbid state of the brain is, however, liable to increase beyond the limit above adverted to, and then the usual phenomena dependent on severe cerebral disease are manifested. It is well known that lunatics are subject in a much greater proportion than other persons to apoplexy, palsy, epilepsy, and all the trains of symptoms depending on different degrees or modifications of cerebral congestion.

Another mode by which madness brings on a fatal termination is by the exhaustion arising from continued excitement. There are many cases of maniacal disease in which the ceaseless excitement of the feelings, the constant hurry of mind and agitation of body, the total want of rest and sleep, and the febrile disturbance of the system which frequently ushers in the attack of madness, and is always a prominent feature in cases of this description, bring on a very marked reduction of strength as well as of flesh: the degree of emaciation is sometimes extreme. Generally this state of excitement gradually abates, or the means adopted to lessen it and tranquillize the system are attended with success; but this is not uniformly the case, and some maniacs die completely worn out and exhausted. It is in part owing to this cause that the mortality among lunatics is more considerable during the two first years from the period of their attack than in the succeeding years, a fact which appears to be established by the calculations of M. Esquirol. In the Salpêtrière the number of deaths is even much greater in the first year than in the second. Of 790 lunatics who died in that hospital between the years 1804 and 1814, it appears that 382 died in the first ycar from their admission, 227 in the second year, and 181 during the seven succeeding years.

Many lunatics are carried off by diseases of the abdominal and thoracic viscera, which are complicated with madness. Pathology does not enable us to explain the connection between organic diseases of the lungs or bowels and disordered action of the encephalon, and hence many have been inclined to regard the combinations of morbid states to which we now advert as accidental. They are perhaps too numerous to be attributed to chance. The combination of madness, as well as of some other diseases of the brain and nervous system, with diseased states of the liver and of the intestinal canal, was pointed out some years since by the writer of this article. The conjunction of insanity with pulmonary phthisis is a fact established beyond doubt by the observations of M. Esquirol, who remarks that phthisis often precedes the appearance of melancholia, or accompanies it. The disease of the lungs is in these instances latent; the patients lose their strength, become emaciated and suffer under slow fever, sometimes attended with cough and diarrhœa; the phenomena of madness rather increase than abate under these circumstances, and continue until death. On the examination of the body, the lungs are found tuberculated or affected by melanosis.

Diseases of the heart are not unfrequently complicated with madness. We are assured by M. Foville, that of the bodies of lunatics which he examined after death during three years, five out of six displayed some organic disease either of the heart or the great vessels. This was very frequently hypertrophy of the heart. These morbid changes, however, are probably, as M. Foville has observed, more frequently results of the continued agitation, the violent efforts and cries, which in such patients bring on diseases in the thoracic organs, than predisposing causes of cerebral disorder

Diseases of the intestinal canal, whether they exist or not at the onset of the maniacal attack, are subsequently among the frequent causes of death. A state of obstinate constipation often continues for a long time, attended by its usual accompaniments. It gives way, and is followed by or alternates with diarrhœa, which wastes the strength of the patient and terminates in a fatal dysentery. When the body is examined, the intestines are found sometimes distended and loaded with indurated matter, at others empty and pale, with disease of the mucous coat, discoloured and abraded patches or ulceration, and gangrenous spots.

In protracted cases death either results from increase in the disease of the brain, which up to a certain degree had only subverted the operations of that organ subservient to the mental function, and at length becomes incompatible with the merely physical functions of the same viscus; or it is the result of accidental disorders, which, owing to the peculiar state of the brain and other organs in lunatics, are more than usually fatal.

Fatuity or inveterate lunacy becomes complicated with paralysis. M. Esquirol says that of the number of persons who die in a state of lunacy, one half are paralytics. This paralysis of the demented is a peculiar affection, for we are not now referring to hemiplegia, attacks of which are liable to occur at all periods of madness, either ushered in by apoplexy or without it, and which frequently carry off maniacal patients. The general paralysis to which lunatics in the advanced stage are most subject shows itself first in the muscles of articulation; patients have some difficulty and imperfection in speech, which is in the beginning so trifling as to escape those whose attention is not particularly directed to the circumstance. The muscles of the limbs and trunk become subsequently affected; the patient walks with a tottering or shuffling gait, and his trunk is bent forward; his hands shake; his limbs become emaciated and feeble; sometimes he bends towards one side, and at length passes his time in a sitting posture, and bent forward, or takes to his bed when the sphincters gradually lose their power,

sloughs take place about the back, the sacrum, and elbows, followed by gangrene and death.

Many lunatics in the advanced stage labour under a degree of cachexia bordering on scurvy. The skin is beset with scaly or papular eruptions, or discoloured in patches; furunculi appear in different parts of the body, which are much disposed to become sloughy; the gums become red and sore, and bleed; the surface of the body is cold with a clammy perspiration; diarrhœa, and abdominal pains accompany these symptoms; the patient apparently suffers under defective nutrition and a gradual decay of physical life, and dies in a state of extreme emaciation or marasmus.

The preceding are perhaps the natural sequelæ of the diseases under which lunatics suffer in connexion with their original complaint. A great number, however, are carried off by disorders which may be considered as accidental, but to which the condition of body in patients of this description renders them more than other individuals liable. Fevers which assume more or less of the typhoid character, severe catarrhs, and pulmonary affections, are the most frequent of them. It will be supposed that fevers which affect the brain are fatal to lunatics, and such is the fact in a very marked degree.

The diagnosis of accidental diseases in lunatics presents, as M. Georget has well observed, remarkable difficulties. Some patients of this description are continually making unfounded complaints, deceived by their erroneous or fancied sensations. On the other hand, many lunatics labour under very severe affections without revealing them by an expression, either because these affections are latent and do not occasion suffering, or because the disturbed state of their minds does not allow their sensations to reach the centre of perception. In this last relation the medical treatment of lunatics is much more obscure and difficult than that of young children, because the latter are conscious of their ailments, and express them by their cries. "When we observe a lunatic, who had previously been agitated and furious, become morose and taciturn, and at the same time lose his appetite, seek repose, and display a suffering and dejected expression, we ought to examine him carefully: he is threatened with some acute disease. The development of symptoms will soon point out the seat and nature of the complaint, and consequently by what sort of means it is to be opposed. But chronic affections are so slow in their approach and concealed in respect to their symptoms, that they often reach to a very advanced stage before their existence is suspected, unless the organs affected are examined before their diseased condition has manifested itself. We find the lungs full of tubercles, with cavernous excavations and abscesses, or in a state of atrophy, in the bodies of individuals who had neither coughed nor expectorated, nor experienced pain or dyspnœa during life; they had become gradually debilitated, had taken to their beds, and after a continually increasing emaciation, had at length sunk. The disorganization of the lungs had only been discovered by the aid of auscultation and percussion. We must not then wait for the expression of complaints on the part of lunatics in order to have our watchfulness excited to the means which are necessary for preserving their existence."

SECT. IV. — **Of the Causes of Insanity.— Predisposing Causes.**

1. *Natural Constitution.*—Among the circumstances in the previous condition of an individual which prepare him for sustaining the attack of this disease, the most important is a certain peculiarity of natural constitution. This consists chiefly, as it is probable, in a particular organization of the brain and nervous system, rendering those individuals so constituted liable to become insane when exposed to the influence of certain agencies, which in other persons either give rise to a different train of morbid phenomena, or are, perhaps, devoid of any injurious effects. The constitutional peculiarity which predisposes to madness is not distinguished by any remarkable external characters. That such a natural tendency, however, actually exists, and in all instances is a necessary condition to the development of maniacal disease, is to be inferred from the consideration that similar exciting causes exert their influence on other persons without producing a like effect. Among the agents that give rise to madness, there is none more influential than intemperance, or the frequent use of ardent spirits. A considerable proportion of lunatics in the lower classes of society owe their disease to this cause. But it is only in a certain proportion of persons addicted to intemperance that the phenomena of madness make their appearance. Others, under the influence of the same noxious cause, are affected with apoplexy or paralysis; in many, the brain escapes and the liver becomes disordered, or dropsy takes place, with or without disease of the liver; in some, the lungs become the seat of morbid changes. It is evident that there must be an original difference in the habit of body whence arises the diversity of results brought about by the same or very similar external agencies. This original difference is apparently a peculiarity in the congenital constitution of each individual. It may be transmitted from parents, or it may arise *de novo*, as other varieties in the congenital structure are known to do. Hence it is comparatively of little moment, as far as an individual is concerned, to inquire whether his morbid predisposition has been derived by hereditary descent, or has sprung up with himself. It may, indeed, be observed that peculiarities which arise in a race are often common to several individuals even in the first generation. Albinos, for instance, though the offspring of parents of ordinary complexions, very frequently have brothers or sisters resembling themselves. In like manner, diseases which appear for the first time in a family often affect several members of it, who partake of the same peculiarity of temperament or congenital structure.

If these remarks are well founded, it must be apparent that hereditary madness is not less curable than a disease having symptoms of the same description, which has not been previously observed in the family of the person affected by it.

That the predisposition to madness, when it has once arisen, is frequently transmitted, is a fact too well established to admit of doubt; it constitutes a feature in the history of the disease.

The hereditary transmission of this tendency is

remarked by M. Esquirol to be more general among the opulent than the lower classes. He states the proportion of hereditary cases among the former to be one-half, among the latter to be one-sixth. This, however, seems to be a mistake, as it appears by his table that of 351 cases at the Salpêtrière, 105, or nearly one-third, had the disease by inheritance. Among 264 patients of a superior class 150 cases were, according to the same writer, hereditary. He accounts for this difference by referring to the exclusive marriages of aristocratical families, a cause which had formerly in France much influence. It remains to be determined whether the same difference is to be observed elsewhere under circumstances not admitting this explanation.

The same writer affirms that persons born before their parents had become maniacal are less subject to mental disease than those who are born after the malady had displayed itself. He makes a similar remark as to those who inherit the disease only on one side, in comparison with persons whose paternal and maternal ancestors had been affected by it. According to Burton the offspring of parents advanced in years are more subject than others to melancholy madness.

Another observation relating to the hereditary transmission of this morbid tendency is, that the disease is apt to show itself in different individuals of a family at a particular period of life, and in all of them under a similar character. M. Esquirol has made this remark, and he has mentioned several facts in illustration of it. "Two sons of a merchant of Switzerland died insane at the age of nineteen years. A lady, aged twenty-five years, was attacked by puerperal madness; her daughter suffered in like manner at the same age. In one family the father, the son, and the grandson, all committed suicide about their fiftieth year. There was at the Salpêtrière a prostitute who had thrown herself into the river seven times; her sister drowned herself in a fit of intoxication. There exists near Nantes a family in which seven brothers and sisters are in a state of dementia. A gentleman, affected by the first events of the Revolution, remained during ten years shut up in his chamber. His daughter, about the same age, fell into a similar state, and refused to quit her apartment. This predisposition, which manifests itself by external signs, by peculiarities in the moral and intellectual character of individuals, is not more surprising in connection with madness than are the instances of gout, of phthisis pulmonalis, and other diseases, in a different point of view. It may be traced from the age of infancy: it furnishes the explanation of a multitude of caprices, irregularities, and anomalies, which at a very early period ought to put parents on their guard against the approach of insanity. It may furnish useful admonitions to those who preside over the education of children. It is advisable in such cases to give them an education tending to render the habit robust, and to harden it against the ordinary causes of madness, and particularly to place them under different circumstances from those with which their parents were environed. It is thus that we ought to put in practice the aphorism of Hippocrates, who advises to alter the constitution of individuals in order to prevent the diseases with which they are threatened by the hereditary predisposition of their family."

M. Esquirol affirms that many facts have occurred within the sphere of his information proving a strong predisposition to madness to have arisen from some accidental fright sustained by the mother during pregnancy. Marked cases of this description are said to have occurred during the period of the Revolution.

2. *Age.*—Persons in the middle period of life are most subject to attacks of insanity properly so termed. M. Esquirol has remarked that imbecility is the predominant mental disorder of childhood, mania of youth, melancholia of more advanced manhood, and dementia of old age.

The years during which madness most frequently makes its first appearance are those between thirty and forty in the age of the individual; next to these are the years between twenty and thirty; thirdly, are those between forty and fifty. Insanity is comparatively rare in the earlier as well as in the later periods. The case, however, of a child who had been maniacal from the age of two years was noted by Joseph Frank at St. Luke's in 1802. M. Esquirol mentions besides three instances of maniacal children. Dr. Haslam and others have reported some cases of the same description, but they are not of frequent occurrence.

M. Georget has observed that out of the number of 4409 lunatics in different hospitals in France and England, 356 were between the ages of ten and twenty, 106 from twenty to thirty, 1416 from thirty to forty, 861 from forty to fifty, 461 from fifty to sixty, 174 from sixty to seventy and only 35 upwards of 70.

The following table, given by Dr. Burrows from Reports of the French hospitals, tends further to illustrate the proportional frequency of madness at different periods of life, and it has the advantage of distinguishing the sexes.

Ages.	Men.	Women.	Total.
From 10 to 19 —	78	62	140
20 to 29 —	198	267	465
30 to 39 —	248	324	572
40 to 49 —	231	290	521
50 to 59 —	132	218	350
60 to 69 —	119	146	265
70 to 79 —	76	101	177
80 to 89 —	7	4	11
Ages unknown.	6	0	6
	1,095	1,412	2,507
Under 50 years of age.	755	943	1,698
Above 50 years of age.	340	469	890
			2,507

3. *Sex.*—If we may believe Cælius Aurelianus, madness was among the ancients more frequent in males than in females. In France, according to M. Esquirol, the reverse of this statement is true. This writer attributes the greater comparative liability of modern females to the vicious system of modern education, to the preference given

to mere accomplishments, to the reading of romances, which gives to young persons a precocious sensibility, premature desires, and ideas of perfection which they nowhere find realized, to the frequenting of plays and assemblies, the abuse of music, and want of occupation. In England, he observes, where women have an education more strengthening to the mind, and where they lead a more domestic life, the proportion of female lunatics to the male is less considerable. These considerations may account for the facts in respect to the higher orders; but as the observation includes those who are the inmates of hospitals, we must have recourse, in order to explain it, to the physical circumstances in which the condition of females differs from that of the male sex. The difference is in fact so great in France, that M. Pinel, in 1802, calculated that there were two female to one male lunatic. According to the report "Sur le service des aliénés," by M. Desportes, made at Paris in 1823, it appeared that from 1801 to 1821 the number of males admitted at the Bicêtre was 4552, and that of females at the Salpêtrière during the same period, 7223. At Bethlem, according to Dr. Haslam, 8874 lunatics were admitted in the course of forty-six years, of whom 4832 were females, 4042 males. At St. Luke's, according to a statement made to a committee of the House of Commons in 1807, the number of females is usually greater than that of males by about one-third. In comparing a number of statements from different countries, M. Esquirol, however, concludes that the excess in the proportion of female lunatics is not so considerable as it is generally supposed to be, and that it does not, in fact, greatly exceed the difference which exists between the sexes in the ordinary state of the population. It is greater in some countries than in others, and in France than in England.

[Taking the result of inquiries in various parts of the civilized world, it would not seem that there is much difference between the sexes. Of 76,526 cases, enumerated with this view, 37,825 were males, and 38,701 females,—the ratio of males to females being thus as 37 to 38 nearly.]

4. *Celibacy.* — M. Georget was inclined to reckon celibacy among the predisposing causes of madness, from considering the following facts detailed in the report of M. Desportes.

Out of 1726 female lunatics 980 were single women, 291 were widows, 397 were married persons.

Out of 764 males 492 were single, 59 were widowers, and 201 were married.

These relative numbers appear remarkable, but in estimating the result we must take into our account the fact that married persons lead in general more regular lives than the unmarried, that they are generally more fixed in their pursuits and their condition as to maintenance and employment, and less subject to causes which agitate the mind and excite strong emotions. These remarks apply, however, principally to men, and the difference is equally great among females.

5. *Temperament.*—A constitution of body predisposing to violent passions also predisposes to madness.

With respect to complexion, which is generally supposed to denote varieties of temperament, it does not appear that there is any particular shade or hue of eyes or hair which marks a predisposition to this disease. On a comparison of facts collected from several countries, M. Esquirol has not been able to discover any decided difference. In the Parisian hospitals a chestnut colour of both eyes and hair prevails, which is the general colour among the people of the north of France.

6. *Season.* — M. Georget has given briefly the result of reports indicating the influence of seasons. It seems that during the six summer months a greater number of persons are received into the lunatic asylums than in the six months of winter.

[According to Dr. Woodward, (*Eleventh Report of the State Lunatic Asylum at Worcester, Mass.*, p. 41, Dec. 1844,) there were in winter the least number of admissions, the fewest discharges, and the fewest deaths.

M. Andral (*Cours de Pathologie Interne*) estimates the average frequency of insanity in the different seasons in the following order—summer, spring, winter, autumn. This applies especially to mania. Monomania and dementia appeared to occur equally at all seasons. In Naples, monomania was observed to be more frequent in the month of September.

As regards the termination of the disease, some have assigned the greatest number to autumn, and the greatest mortality to December, January, and February.

6*. *Moon.* — Not many years ago, it was universally believed that the full moon exerts a decided influence on the insane; hence the names *lunatic, moon-struck*, &c., applied to these unfortunates. It is now, however, settled by the observations of Drs. Haslam, Esquirol, Woodward, and others, that if the *light* of the moon be excluded, the insane are not more affected at the full of the moon than at any other period. Nor is the common idea of a direct influence of the sun at the summer solstice better founded. The whole effect, in the first case, seems to be induced by the stimulus of light; and in the latter, by that of heat;—the two being conjoined at the summer solstice, in consequence of the length of the days at that period. (See on this subject, the writer's *Human Health*, p. 184, Philad. 1844, and Dr. Woodward, op. cit., p. 67, Boston, 1844.)]

7. Among the most powerful of the causes which render persons obnoxious to madness, must be reckoned previous attacks of the same disease. When such attacks have been repeated, the predisposition becomes increased. There are instances, however, of persons who, during a certain period of their lives, have been subject to repeated attacks of maniacal disease, but have recovered entirely, and have lived many years in a state of perfect sanity.

8. Other diseases of the brain, such as apoplexy and paralysis, sometimes predispose to madness, or are followed by it. Epilepsy of a severe and inveterate kind is sometimes complicated with insanity. These cases are distinct from the fatuity which is often the result of long-continued epilepsy. The form of maniacal disease connected with epilepsy is peculiar, and this may be considered as constituting a distinct disease. It

has been ably described by the late Dr. Edward Percival.

9. *Education.*—An erroneous and unsuitable method of education is among the most influential causes of insanity. There are two different points of view under which the injurious effects of wrong education may be considered. By too great indulgence and a want of moral discipline, the passions acquire greater power, and a character is formed subject to caprice and to violent emotions: a predisposition to insanity is thus laid in the temper and moral affections of the individual. The exciting causes of madness have greater influence on persons of such habit than on those whose feelings are regulated. An overstrained and premature exercise of the intellectual powers is likewise a fault of education which predisposes to insanity, as it does also to other diseases of the brain. These are two considerations which are of the greatest importance with respect to the welfare of families to which an hereditary constitution may belong, rendering them more liable than others to cerebral diseases. They are distinct in themselves, and each might furnish a theme for an extensive treatise, most valuable in a practical point of view. Under the first head it would be necessary to consider the efficacy of those plans of education of which the professed object is to form a character remarkable for sedateness, for the strict discipline of the feelings, and, as far as this is attainable, for the abolition of strong passions and emotions. Such, undoubtedly, would be the kind of moral education best adapted for those who are constitutionally liable to insanity. The second remark, on the regulation of mental exercise in young persons whose nervous systems are feebly constituted, has a more extensive bearing than on the subject of insanity. It brings forward a suggestion which is of general interest in these times in which mental exertion is stimulated to the utmost, and when, in reality, all the physical and moral powers are sacrificed to the cultivation of intellect, or in many instances to the mere acquisition of knowledge.

Exciting Causes of Madness.—The immediate causes of madness are in part physical agents, and in part moral. Perhaps it may be remarked that the former are the most prevalent causes of madness in the lower ranks of society, and the latter in the higher class, whose intellects are more developed, and whose minds are subjected to more extensive influences.

1. Among physical causes of madness, one of the most frequent is the immoderate use of intoxicating liquors. There is hardly a tribe of the human race who have not succeeded in inventing some method of producing intoxication. Ardent spirits are perhaps, of all, the most injurious in their effects, particularly on the lower classes in the northern countries of Europe and America. It has been repeatedly observed that a large proportion of the cases admitted into pauper lunatic asylums arise from this cause. They are in general to be reckoned among the cases most easily cured; for, although this is not uniformly the fact, it often happens that when the exciting cause is removed, the effect begins to lessen, and eventually ceases. When these patients are prevented from obtaining stimulating liquors, and are treated with sedative remedies, they quickly show signs of amelioration and the subsidence of disease.

The use of opium and other stimulants is among the exciting causes of madness, though of much less general agency than the ordinary means of intoxication.

[Alcoholic liquors are a common cause of one form of delirium—*delirium tremens;* but, so far as the writer has observed, not of insanity. In this country, where delirium tremens has prevailed to a great extent, and where a good opportunity exists for noticing the effect of alcohol in inducing insanity, the writer's experience has not exhibited to him a great many that could be unhesitatingly referred to it. The fact, too, of the number of insane among the Society of Friends, who rarely indulge in any form of alcohol potations, is, so far as it goes, against the idea of alcohol being an extensive cause of mental alienation. It is proper to add, however, that in the Reports of most of the insane asylums, intemperance is recorded as a common cause.]

2. Blows on the head, and exposure to ardent solar heat, are well known to be occasionally the exciting causes of madness. It is plain that they act by bringing on inflammation, or a state bordering on inflammation, in the encephalon. The same remark may be made with respect to mercury, as used in syphilitic diseases. It is probably an error to suppose that syphilis is itself a cause of madness.

3. *Intestinal Irritation.*—A disordered state of the intestinal canal often becomes a cause of disturbance in the brain, by whatever antecedents the former disease may have been induced. The state of the intestinal canal, to which we allude, is itself much more frequently of an inflammatory nature than it has generally been imagined, or at least than it was formerly supposed to be. In that condition of the canal which gives rise to costiveness, alternating with diarrhœa, and accompanied with indigestion, flatulence and eructations, anorexia and nausea, transient but often acute pains in the hypochondria, livid and yellow suffusions of the skin, viscid secretions in the mouth, or redness of the fauces and palate, with a glazed and dry surface, the whole train of symptoms often depends upon a low degree of chronic inflammation in the mucous membrane of the intestinal canal; and this is perhaps a frequent, if not an ordinary state in those cases in which disorders of the nervous system supervene on complaints of the stomach and bowels. This form of disease has been described by Dr. Ferriar and several other practical writers; but it is to M. Broussais that we are indebted for a more ample development of its pathology.

The enteric disorder, which lays the foundation for maniacal symptoms, as well as for other affections of the nervous system, is the result in different instances of various and very diverse noxious causes. The most frequent is excess in the use of stimulant and indigestible food. Too great indulgence of the appetite among the more opulent, and among the lower classes long-continued constipation, unwholesome diet, the use of salt provisions, exposure to cold and want, or neglect of warm clothing, give rise to diseases of the same description.

Intestinal worms are one of the results of constipation. Madness produced by the last mentioned cause is probably of very rare occurrence. M. Esquirol has, however, mentioned a remarkable instance of maniacal disease, affecting a young man, who was cured at two different periods by the expulsion of a large quantity of worms from the intestinal canal.

4. *Causes depending on States of the Uterine System.*—States of the general system connected with irregularity of the uterine functions are well known to coexist with or to display themselves in various affections of the brain. Among them madness is one. Maniacal affections of this class may be mentioned under three heads.

a. Dysmenorrhœal Affections.—Some females at the period of the catamenia undergo a considerable degree of nervous excitement: morbid dispositions of mind are displayed by them at these times, a wayward and capricious temper, excitability in the feelings, moroseness in disposition, a proneness to quarrel with their dearest relatives, and sometimes a dejection of mind approaching to melancholia. These are distinct from the cases of hysterical affection connected with the same periodical causes of excitement. The former are sometimes the preludes of a far more permanent disease.

b. Suppressions of the Catamenia. — Sudden suppressions of the catamenia are frequently followed by diseases of the nervous system of various kinds. Females exposed to cold, undergoing powerful excitements, sustain a suppression of the catamenia, followed in some instances immediately by fits of epilepsy or hysteria, the attacks of which are so sudden as to illustrate the connection of cause and effect. In attacks of madness the catamenia are for the most part wholly or partially suppressed during the early periods, and in many cases it is not easy to say whether the suppression is the effect or the cause of the disease. There are instances, however, in which the circumstances sufficiently indicate the order of connection. Dr. Burrows has detailed a case in which suppression brought on by manifest causes was followed by mania. We have already alluded to the case of a young female mentioned by M. Esquirol, who suddenly exclaimed that she was cured of her disorder; her catamenia had flowed spontaneously, and her restoration to sanity was the immediate consequence. Facts so decisive in their bearings on pathology are not of very frequent occurrence, but their evidence reaches farther than the individual cases recorded.

It often happens that after some weeks or months in the duration of madness, the catamenia, though previously deficient, become restored nearly to their usual state. This, like the other indications of improvement in merely physical health, is only a favourable sign when it is accompanied by some amendment in the state of the mental faculties. Without any such change, it rather gives reason to apprehend that the disorder is becoming inveterate, and perhaps already making its transition from mania into an incipient stage of fatuity.

c. Puerperal madness is another modification of the disease connected with the state of the uterine functions. As this form of insanity is a most important subject, and in circumstances very peculiar, we shall allot a distinct section towards the conclusion of this treatise to the consideration of its history and pathology.

4*. [Excessive venery has been regarded by many as a cause of insanity, and especially of dementia. In the annual reports of several of our insane institutions and penitentiaries, many cases are referred to masturbation; yet its influence would certainly seem to be exaggerated by some observers. It is a common vice everywhere, and is very likely to be practised to a greater extent in such institutions; but it cannot be considered as by any means proved, that masturbation was the cause of the insanity in many of the reported cases. Often, doubtless, it is the effect.

A table of the causes assigned for insanity in different insane institutions of Great Britain and this country is given by Dr. Woodward, in the *Eleventh Report of the State Lunatic Hospital at Worcester, Mass.*, Boston, 1844.]

5. *Metastasis.*—The pathological fact, that diseases of the brain, and among others that from which madness results, supervene on the cessation of various discharges, on the healing of old ulcers, on the disappearance of cutaneous eruptions, on the cessation of inflammatory disease in membranous and other structures, on the removal of tumours, has been observed with greater or less attention by practical writers on medicine from the time of Hippocrates. Many cases illustrative of this fact are to be found in the works of Hildanus, Tulpius, and Hoffmann; and Sauvages, among the forms of madness, has reckoned one which he terms metastatic. M. Esquirol says that even a cessation of the usual discharge from the nostrils, of leucorrhœa, of blennorrhagia, as well as the disappearance of scabies, of herpes, of gout and rheumatism, has produced madness. In general it may be observed that the suppression of acute eruptions, whether pustular, exanthematic, or erysipelatous, is followed by acute inflammatory affections of the internal organs; in such cases the brain or its membranes are attacked by phrenitis or meningitis; while the disappearance of chronic disorder of the same class is the precursor of mental aberration. The suppression of more copious discharges, the removal of large tumours, the disappearance in dropsical cases by rapid absorption of deposited fluids without increased excretion, has been followed by determinations of blood to the head, giving rise to fatal apoplexy or severe convulsions.

6. *Moral Causes of Insanity.* — Among the moral causes of insanity we must reckon all the circumstances which are calculated to give rise to strong emotions, or to excite the passions. Strong emotions, by their operation on the nervous system, produce injurious effects on the brain, and give rise to disturbed actions in that organ, whence arises mental derangement. The passions and emotions are indeed the principal and most frequently productive causes of madness.

In barbarous nations, among whom the mind is uncultivated, the passions are proportionally impetuous, but their sphere is limited, and the intellectual and moral faculties are very imperfectly developed. Madness is comparatively rare among such nations. According to Von Humboldt there are very few lunatics among the native Ameri

cans, and a similar observation has been made with respect to other uncivilized tribes. In Russia, Turkey, and China, madness is unfrequent. In the hospital of Grand Cairo, a city containing 300,000 people, M. Desgenettes found only fourteen lunatics. It must, however, not be forgotten that in such places many deranged persons are suffered to wander about through neglect and the absence of regulations for police, and that their numbers thus escape observation; yet this circumstance is not sufficient to account for the entire difference between barbarous and civilized countries, in respect to the apparent frequency and rarity of madness. It might be affirmed that mental derangement is the result of a deviation from the state of nature, if we were to agree with those who look upon barbarism as the natural condition of our species, and represent all that is ennobling and exalted, all that is good and really desirable in human life, as foreign or accidental, and the produce of forced and unnatural culture. In this as in other instances, it has pleased Providence to mix up with the greatest blessings some portions of evil, some ingredients of intense suffering: "Medio de fonte leporum, Surgit amari aliquid, quod in ipsis floribus angat."

[It has been maintained, that the number of the insane is in a direct ratio with civilization; but the medical statistics of countries do not exactly establish this; although there can be no question, that civilized man is more subject to insanity than the savage. From estimates made by M. Brière de Boismont, it would appear, that in England the proportion of the insane to the whole population is 1 in 783; in Wales, 1 in 911; in Scotland, 1 in 573; in the Rhenish provinces, 1 in 1000; in Norway, 1 in 551; in France, 1 in 1000; and in Italy, 1 in 3785; yet it would scarcely be admitted, that the people of Norway are more civilized than those of France. The proportion of insane in the larger cities has been enumerated as follows: London, 1 in 200; Paris, 1 in 222; Milan, 1 in 242; Florence, 1 in 238; Turin, 1 in 344; Dresden, 1 in 466; Rome, 1 in 481; Naples, 1 in 791; St. Petersburg, 1 in 3133; Madrid, 1 in 3350; and Grand Cairo, 1 in 30,714. There is certainly a singular difference between these countries, as there would appear to be between the different states of this Union in the number of the insane; and the difference is by no means easy of explanation. In New Hampshire, when the population did not exceed 280,000, the number of lunatics was estimated at 600; in Connecticut, in a population of 298,000, at 700; in Massachusetts, with a population of about 612,000, there were 1000; and in Virginia, taking the population at 1,200,000, it is estimated that there were, in 1838, not fewer than from 600 to 800 insane persons. In New York, the ratio in 1835 was considered to be 1 in 887 and a fraction; and the probability is, that it is quite as great in Pennsylvania, where, under the lowest estimate, there were probably in 1841 not fewer than 2000 persons, lunatic and idiotic, of whom, it has been estimated, that about 1200 may be idiots. The census of the United States has not been taken with sufficient accuracy to enable us to deduce any satisfactory results.]

Various kinds of mental excitement have different degrees of influence in producing madness, under different social and political circumstances. Among the patients of the Salpêtrière, in 323 cases admitted during the years 1811, 1812, M. Esquirol reckoned 105 originating in domestic chagrins, 77 occasioned by poverty and reverses of fortune, 45 by disappointments in love, 38 by fright, 8 by fanaticism. Cases of what is termed religious madness are supposed to be much more frequent than this small proportion seems to imply, but it is much to be desired that we could determine the meaning of the expression religious madness, and to what examples of disease it may be correctly applied.

There can be no doubt that madness has often been produced by a vehement and impassioned style of preaching. "In the kingdom of Naples," says M. Berthollet, "a custom exists of preaching in favour of missions by a particular set of priests. In order to animate the faith of believers, they accompany their orations with particular acts, which are often of such a nature as to produce too powerful an effect on weak minds. They hold their hands over flaming torches, and whip themselves with scourges garnished with iron points. Their sermons are prolonged till the close of day, and the feeble glare of a few flambeaus heightens the effect of the scene." "One of these sermons gave occasion to the case I am about to describe. The subject was *hell:* to heighten the colouring of the frightful picture which the preacher had traced, he took a skull in his hand, and having raised a question as to the abode of the soul to which it belonged, he exclaimed, invoking it, 'If thou art in heaven, intercede for us; if thou art in hell, utter curses.' He then cast it from him with violence. The lady, whose case is subsequently described in M. Berthollet's memoir, was instantly affected by a morbid change in the nervous system.

Strong emotions excited by vehement preaching produce continually in females and very sensitive persons, fits of hysteria, and in those who are predisposed to mania there can be no doubt that similar causes give rise to attacks of madness. Cases, indeed, are of continual occurrence which establish the fact.

But the terrors excited by a troubled conscience, which have given birth in the imagination to gorgons and chimeras, and monsters of darkness, are sufficient of themselves to produce madness in persons predisposed. None can entertain a doubt on this subject who recollect the stories of men persecuted by the Furies, the appalling self-tortures and mutilations, the blood-stained altars and the hideous divinities, the sacrifices of wives and daughters, the gloomy and hopeless fatalism of the pagan world. There is no remedy for these evils, resulting as they do from the moral and physical disorders of human nature, but the mild and consoling influence of Christianity; and if this religion has been made in some instances the instrument of evil rather than of good, we must recollect that the greatest blessings are capable of becoming by perversion the fertile sources of severe calamities. Perhaps some persons may suppose that if it were possible to divest the minds of men of all religious anxieties at once, together with all belief, they would be gainers by the

change. But this experiment has been already tried in France, in a great part, during one period of the Revolution, and the following remarks of M. Esquirol display the results, as far as they relate to the increase or lessening of insanity.

"The changes," he observes, "which have taken place during the last thirty years in our moral sentiments and habits, have produced more instances of madness in France than all our political calamities. We have exchanged our ancient customs and fixed habits, our old and established sentiments and opinions, for speculative theories and dangerous innovations. Religion now only comes forward as a formal usage in the solemn transactions of life; it no longer affords its consolations to the afflicted, or hope to the desponding. Morality founded on religion is no longer the guide of reason in the narrow and difficult path of life. A cold egotism has dried up all the sources of sentiment; there no longer exist domestic affections, respect, attachment, authority, or reciprocal dependencies; every one lives for himself; none are anxious to form those wise and salutary provisions which ought to connect the present age with those which are destined to follow it."

Sect. V. — **Necroscopical Investigations of Madness.**

Recourse has been had to anatomical investigations with a view to illustrate the pathology of madness, and although such researches have not answered fully the expectations with which they were entered upon, they have led to results by no means devoid of interest in their physiological bearing, and capable, though to a limited extent only, of practical application.

This department, as well as most others, of pathological anatomy, may be said to begin with Morgagni. That celebrated writer has, however, related the details of but seven or eight dissections referring to cases of insanity. In these he remarked several facts which later observations have confirmed. He found the substance of the cerebral hemispheres more firm, and that of the cerebellum softer than natural. In one instance the white substance of the cerebrum was hard and of a brownish hue, and its blood-vessels, as well as those of the plexus choroides, much distended with blood: in another there was hardening of the hemispheres and softening of the fornix, fulness of the cerebral vessels, adhesion of the pia mater: in a third, injection of the meninges and the plexus, hardening of the brain, and softening of the cerebellum. This writer mentions also collections of serous fluid in the ventricles and in the tissue of the pia mater.

The researches of Greding were much more extensive, and his observations more various. Among the facts remarked by him are thickenings of the cranium, either partially or generally observed in 167 ordinary maniacal cases out of 216, in 78 out of 100 cases of raving madness, and in 22 out of 30 cases of idiotism or imbecility; softness of the brain in 51 cases out of 100, especially in mania complicated with epilepsy; wasting of the optic thalami in two cases of dementia; enlargement and contraction of the ventricles; serosity in these cavities, or dryness of their surfaces; adherence of the dura mater to the skull; thickened and blue colour of the pia mater; softness of the tubercula quadrigemina; osseous or stony concretions in the cerebellum.

Dr. Haslam has given the details of 37 cases of madness with the appearances discovered on dissection. In not one of these cases were the brain and its membranes free from morbid appearances. In almost all, the membranes either bore marks of former inflammation or were distended with blood: in 16 cases there was an effusion of serum between the membranes, and in the lateral ventricles this was observed eighteen times. In nine cases the consistence of the brain was firmer than usual; in seven it was softer, but in 20 not perceptibly altered. In three cases, the cranium was thicker, and in three thinner than the natural state. In several cases a peculiar looseness of the scalp was observed.

The following are the most remarkable of the observations made by M. Esquirol on the morbid appearances of the brain in madness. The cranium thick and compact; in other cases thin and porous; often injected with blood: crania irregular in respect to the different diameters, and to the cavity of the two sides. Membranes thickened in 11, injected in 19 cases. Basilary arteries ossified in 5 cases. Cerebrum dense in 15, soft in 19 cases. Cerebellum dense in 12, soft in 17 cases. Grey substance abundant in five, discoloured in 15 cases. White substance injected in 19 cases. Adhesions of the lining membrane of the ventricles in 54 cases. Serous depositions frequent between the pia mater and the arachnoid, as well as in the ventricles. Plexus choroides displaying almost always serous vesicles, (kystes séreuses.) Many other morbid changes have been pointed out by the same writer, such as tumours, vesicles (kystes), partial softenings and ossifications of the arachnoid. Two cases of acute maniacal disease, observed by M. Esquirol, are recorded by M. Georget, (Art. *Encéphalite*, in the Dict. de Médecine,) in which the brain presented all the characteristics of intense inflammation.

M. Georget has recorded with great precision the facts which he has himself observed. The following are the most remarkable. Irregular conformations of the cranium, the prominences of which are developed irregularly, those of the right side being generally larger than those of the left; some skulls having the lateral diameter of equal extent with the antero-posterior, and the cavities of the base irregular in extent; some skulls, one in 20, thickened partially or generally; more frequently the bones hard, white, without diploë, resembling ivory; some very light. Dura mater rarely changed; sometimes adherent to the skull, thickened, containing deposits of bone. Arachnoid displaying in places additional laminæ of a red or grey colour; sometimes thickened but smooth. Pia mater injected; or thickened and infiltrated with serum, giving at first the appearance of a gelatinous deposit. Volume of the brain sometimes less than the cavity of the cranium seems to require. Some brains very hard, cut with difficulty; the white substance glutinous, elastic, and suffering distension; more frequently the brain is soft, the grey matter being pale and yellowish, and the white substance discoloured, of a dirty white, the colour and consistence of

these portions almost confounded. The convolutions separated by serosity and the pia mater thickened. Interior cavities of the brain appearing in some instances very large, in others small, often filled with a serous fluid remarkably clear and limpid; plexus choroides exanguious, containing hydatidiform vesicles. Partial softenings of the brain; erosions, ulcerations of the surface of the ventricles. Cerebellum generally softer than the cerebrum; sometimes partially softened. Mesocephalon, medulla oblongata, and medulla spinalis rarely display morbid changes of structure.

M. Georget has thus summed up in a short compass the morbid changes which have been observed in the heads of maniacal subjects. 1. Bones of the cranium sometimes thickened, sometimes without diploë, thick and resembling ivory; sometimes light and spongy; inequalities in the form of the cranial cavity. 2. Injections, thickenings, serous infiltrations of the pia mater; separations and attenuations of the cerebral convolutions. 3. Surface of the cerebrum softened and adhering to the pia mater, so that the latter, when pulled off, raises portions of the cerebral substance with it; injected state of the cerebral substance, reddened colour of the grey portion, marbled violet hues in the white portion, increased consistence of both; discoloration and general softening of the cerebrum, grey substance yellowish, white substance of a dirty white; serous collections in the ventricles, particularly in the lateral ventricles; partial softenings. Other alterations are much less frequent; the annular protuberance, and the four great nervous trunks which take their rise from it, the medulla oblongata and the medulla spinalis, are rarely found to have undergone any material change of structure.

Some curious and interesting additions have been made to the morbid anatomy of madness by M. Foville, whose researches were conducted with great accuracy. It was a part of his plan to compare, in every instance on the spot, healthy brains with those which were the subjects of examination as having appertained to maniacal patients. By this method some minute peculiarities of structure seem to have been detected which might otherwise have escaped notice. M. Foville's inquiries were carried on at the Salpêtrière in conjunction with his colleagues, MM. Delaye and Pinel Grandchamp, when that hospital was under the superintendence of M. Esquirol, and subsequently by himself at the establishment of the Lower Seine, an extensive receptacle for lunatics, which has been for some years under his immediate care. His observations are arranged under the following heads; 1. morbid changes in the cortical substance; 2. changes in the white or fibrous substance; 3. changes in the nerves of sensation; 4. changes in the membranes; 5. observations on the skull and the hairy scalp; 6. changes observed in idiots. We shall abstract the most remarkable phenomena noticed under several of these divisions.

1. *Changes in the grey substance.*—In the most acute cases the surface of the cortical portion presents, on the removal of the membranes, a most intense redness, approaching to that of erysipelas. This is still more marked in the substance of the grey matter itself; it is more striking in the frontal region than on the temporal lobes, and in the higher regions than in the posterior parts of the brain. In brief terms the morbid changes observed by M. Foville in *acute cases of madness* are nearly confined to the following: "Red colour, uniform and very intense; numerous mottled spots, varying from a bright to a violet red, bloody points, minute extravasations of blood; diminished consistence in the thickness of the cortical substance, coincident mostly with a slight increase of consistence in its surface; dilatation of the vessels, resistance of their parietes." In acute cases M. Foville has never observed adhesions of the membranes to the cortical substance. Such adhesions are very frequent in chronic cases, and hence, as he conjectures, may be explained the curable nature of recent maniacal affections, and the hopeless and incurable state of those patients who have long laboured under madness or dementia.

Among the chronic changes of the cortical substance, the most frequent is a very perceptible increase of firmness and density in the superficial part, extending to no great depth, but uniform, constituting a distinct lamina, smooth externally, but internally irregular, of a lighter colour than usual, which, when torn off, leaves the remainder of the cortical substance red, soft, and mammillated, somewhat resembling granulations. Something like this external pseudo-membrane of the cortical substance has been noticed in wild animals which have died in a state of confinement, by M. Foville, and is conjectured by him to denote a cerebral disease in them. The pale and almost bleached hue of the surface of the cortical portion is always connected with this increased density in its substance. Sometimes the surface is rough and granulated, containing small grains of a yellowish white.

In conjunction with these changes the volume of the convolutions remains natural, or is less than usual. When lessened, there are sometimes linear depressions or irregular pittings on the surface of the convolutions, and in the cortical substance itself there are small yellowish lacunæ filled with a serosity of the same tinge. These lacunæ are supposed to correspond with the minute extravasations observed in acute cases. In other instances the diminution of volume is a real atrophy of the convolutions, which appear thin and angular, as if pinched up towards their extremities. This morbid change corresponds with what MM. Gall and Desmoulins have termed atrophy of the convolutions. It is very frequent in the frontal regions of the hemispheres. It often comprises particularly three or four convolutions on each side of the sagittal suture, a chasm filled with serosity occupying the place left by absorption of the cerebral substance. Co-extensive with this appearance is that species of atrophy in the cranium in which the diploë disappears, and the external lamina approaches the internal, leaving a superficial depression on the head. In these cases of atrophy of the convolutions, the diminution of substance is confined frequently to the cortical or grey matter. What remains of the cortical substance is harder than natural, and sometimes presents, when carefully examined, a really fibrous structure: it is of darker colour, or seems to separate into layers, of which the exterior is pale and the interior of a rose colour.

Another state of the cortical substance observed in chronic cases of madness is that of softening (ramollissement); this is entirely distinct from the softened state of the external portion already described. The whole thickness of the grey substance is equally altered in these cases; its colour is more brown than usual; its consistence almost liquefied.

This extreme and general softness of the cortical substance does not necessarily accompany a similar state in the white substance; it is sometimes conjoined with a hardened state of the medullary portion. In such instances the grey may be separated from the white matter by pouring water upon it. Appearances of this kind seem to belong to cases of the last degree of dementia, with general paralysis and marasmus. M. Foville mentions cases apparently of the same nature, in which limited portions of the grey substance had disappeared previously to death. M. Calmeil, in his work on the paralysis connected with insanity, has related two instances of a similar description.

It seems that the grey substance in other parts of the brain is not subject to a similar change; its morbid alterations coincide with those of the medullary portion. From this remark must be excepted the cortical substance of the cornu ammonis, which is sometimes softened, and at others of a scirrhous hardness.

2. *Morbid changes of the white substance.*—Morbid alterations of the white or fibrous substance in mad persons are in relation to its colour, its density, and its texture.

The white substance is often the seat of vascular injections; sometimes vessels of a certain size being affected, the appearance of bloody points is produced on the section of the white substance. In other instances a finer injection gives rise to a mottled appearance of a deep red or violet colour. A magnifying glass is required in order to discover the vascular injection which produces this appearance. These injections of the white fibrous substance do not always coincide with similar injections of the surrounding cortical substance.

It is not rare to find in lunatics the fibrous substance of a splendid white; this particular aspect generally corresponds with an increased density of the parts. The hardness of such parts of the brain is sometimes almost fibro-cartilaginous. The induration of the medullary substance is, however, not always connected with this remarkable whiteness; sometimes the hardened medullary substance has a yellow tinge or a grey leaden colour. M. Foville attempts to account for this hardening of the fibrous portion of the brain by the supposition that each cerebral fibre has contracted morbid adhesions with the surrounding fibres, so as to render their separation impossible. This opinion is offered as more than conjecture with respect to the different planes of medullary substance, of which it is considered as proved that the white substance of the brain consists. The fibrous mass of the hemispheres results, according to this writer, from the superposition of several distinct layers or planes, applied one upon the other, and connected by means of a very fine cellular tissue. These planes are easily separable in the healthy state, but in the state of maniacal induration they are inseparable.

Among lunatics affected with general paralysis, M. Foville has found these adhesions wanting in only two cases; and in these two instances the cerebral nerves, the annular protuberance, and the medulla oblongata presented an extreme hardness. The same alteration has been found in the brains of old men whose voluntary movements have become uncertain or vacillating; it has never been seen in lunatics whose muscular powers had remained unimpaired.

The brains of some lunatics are so full of serous fluids, that an abundant serosity flows from the surface of incisions; sometimes this serous infiltration is so abundant as to deserve the name of cerebral œdema. A change more rare, which M. Esquirol has remarked, was the presence in the brain of a multitude of small cavities, from the size of a millet-seed to that of a nut, containing a limpid fluid. The section of a brain thus changed is compared to that of a porous cheese. The cavities are supposed to be the sequelæ of extravasations.

The changes in the structure of the cerebellum are analogous in kind to those of the cerebrum, but much more rare.

Tubercles and other tumours in the brain are not considered by M. Foville among the causes of madness properly so termed.

3. *Morbid changes in the Nerves.*—M. Foville is persuaded that he has traced morbid alterations in the nerves corresponding with peculiar phenomena of sensation. In a female lunatic, tormented by hallucinations of sight, the optic nerves were found hard and semi-transparent through a great part of their thickness.

4. *Morbid changes in the Membranes.*—In acute cases the only morbid appearance discovered in the meninges is for the most part injection of the pia mater. This injection is generally proportioned to the degree of inflammation in the cortical substance of the convolutions. The small arteries and veins, passing from the membrane and penetrating the grey matter, are seen distended with florid or black blood: the arachnoid in the mean time preserves its natural aspect.

The chronic changes in the membranes consist for the most part in opacity, increased consistence, thickness of the arachnoid, the formation of granulations, and pseudo-membranes on its surface, and the effusion of serosity into the cellular tissue of the pia mater and the ventricles.

The arachnoid membrane displays either extensively or in patches a pearly whiteness. The opacity never exists without thickening; and in those places where the arachnoid and pia mater are naturally contiguous, they are found to be adherent. These opaque patches, as M. Foville supposes, result from the deposition of albuminous layers upon the arachnoid.

The observations of the same writer on the peculiarities observed in the skulls of lunatics add little to our previous knowledge on this subject; and his remarks on the conformation and texture of the brain in cases of idiotism do not necessarily belong to the subject with which we are now engaged. We shall conclude our abstract of his observations by briefly citing his general inferences.

"The morbid changes which we have surveyed, present many of the anatomical characters of inflammation; intense, general, diffused, redness; in many cases tumefaction; and lastly, in passing to the chronic state, the formation of adhesions between the cortical substance of the convolutions and the contiguous membrane; besides this, adhesion of the different planes or layers of the cerebral substance to each other in a certain number of cases.

"If the simple redness, the perceptible tumefaction—if the general and partial softenings, the increased resistance which we have noted in acute cases, left any doubt of the true nature of the organic disorder, the adhesions observed so often in chronic cases certainly admit of none; and we are forced to allow that there exists in the brains of lunatics a state of true inflammation, unless we cease to regard the adhesions observed in other parts as undoubted traces of such a state, and refuse to admit that adhesions of the pleura, peritoneum, and pericardium, afford evidence of the former existence of pleuritis, peritonitis, and pericarditis.

"As the different traces of inflammation are more constant in the brain than in the membranes, it is necessary to conclude that the essential change has taken place in the brain, and that the change produced in the membranes is only accidentally complicated with it." In his remarks on this subject, M. Foville plainly means to express his dissent from the opinions maintained by M. Bayle, who, in his treatise "Des Maladies du Cerveau," attributes insanity to disease of the membranes.

Among the morbid appearances of the brain, the varied changes of the cortical substance are the most constant in connection with symptoms of mental derangement. Although M. Calmeil maintained a different opinion, and was inclined to ascribe paralysis or the loss of muscular power to disease of the cortical substance, the facts on which he founded this inference do not, as M. Foville contends, warrant such a conclusion. In all instances of the general paralysis of lunatics which he has examined by dissection, there was, besides the change in the cortical substance, some alteration, either hardening, serous infiltration, or softening of the white substance; and in most cases, in addition to these appearances, there were adhesions of the principal planes of the cerebral substance to each other. A very remarkable case which occurred in the clinical course of M. Esquirol in 1823, affords strong evidence in favour of M. Foville's argument. The cerebrum of an idiot displayed the grey substance of both hemispheres in the last stage of atrophy and disorganization, while the white portion of the brain remained perfect on one side. In this person the intellect had been entirely defective, but the muscular power on one side only had failed. From this, and similar observations, M. Foville concludes that the function of the cineritious portion of the brain is essentially connected with the intellectual operations, and that of the fibrous or white structure with muscular action. His two principal inferences are expressed in the following terms:

1st. Morbid changes in the cortical substance are directly connected with intellectual derangement.

2d. Morbid changes in the white substance are directly connected with disorders in the motive powers.

The remarkable accuracy of these researches throws a strong shade of doubt, and even of improbability, over those recorded cases of maniacal disease in which *no morbid* traces were discovered in the anatomical examination. There is much reason for suspecting that a more exact scrutiny, and a careful comparison of the state of the parts with the appearances displayed by the same organ in a natural and healthy condition, might have led, in some of these instances, to the detection of morbid lesions, greater or less in extent. Yet it is not improbable that degrees and modifications of maniacal disorder have taken place, in which such changes might have been, in an early stage, hardly to be traced *with certainty*. In cases of insanity displaying no general disturbance of the intellectual operations, and principally consisting in a morbid state of the temper and affections, and in recent examples of monomania, we should not expect to find strongly marked changes in the brain, and there is indeed but little proof that the brain is in some of these cases diseased. And where there is more considerable disorder in the functions of the brain, arising secondarily or by sympathy with the state of other organs, the traces of such disorder may be very evanescent. It has likewise been remarked by M. Foville, that in some accidental affections of the maniacal class, succeeding the action of debilitating causes, as in the puerperal state, nothing has been discovered in the brain more striking than its extreme and general paleness, and, that although there are in these instances some mottled appearances of a light red or rose colour on the cortical substance, such changes are too slight to be considered as idiopathic. The same writer adds that in the small number of cases of this description which he has had an opportunity of examining, the disorder in the brain has appeared to him to be sympathetic of some deeply-seated disease of the uterus or abdomen. In general, however, the fact is unquestionable that insanity depends upon organic lesion of the brain, and we have sufficient reason to conclude that this lesion is, in its commencement, a degree or modification of inflammatory action.

Sect. VI.—Treatment of Madness.

Division of the Subject.—Moral and Medical Treatment.—The proximate or immediate cause of mental derangement is so much concealed from our research, the phenomena of the disease are so complicated, and the morbid states of the constitution with which they are connected so various, that we might foresee no ordinary difficulty in the attempt to lay down, with respect to this class of disorders, any general principles or indications of cure. In reality this task has been found to be a more arduous one than even the circumstances adverted to would have led us to anticipate; and hence many writers have given it up, and rest satisfied with stating as merely experimental results the effects which particular remedies have been thought to produce.

It is usual to divide under two heads the different means which suggest themselves to our consideration for the cure of madness, and to take up

separately what relates to the moral treatment of the insane, or the means supposed likely to exercise a beneficial influence on the mind; and, secondly, the medical or therapeutical remedies, properly so termed. As this mode of arrangement is attended with some advantages, and as no practical objection has been raised against it, we shall keep it in mind in proceeding to the subject now to be considered, beginning with the medical or therapeutical treatment of insanity.

Medical Treatment of Insanity.—The medical treatment of insanity may be referred in a great measure to two indications or principles, which in many cases may be followed more or less fully, and will in general serve the purpose of associating in the mind the different curative attempts which may be made with some hope of success. There are, indeed, instances of the disease to which these indications are either inadmissible, or can only be adopted in a very limited extent; but such cases may be considered as exceptions.

I. The first indication is to remove or lessen that diseased condition of the brain on which we have reason to believe that madness is, in some part at least, dependent.

That the diseased condition of the brain here referred to is nearly allied to inflammation, that all its essential pathological characters are those of inflammation, may be concluded from the following considerations.

1. The morbid appearances displayed by anatomical researches in the brain and its investments are, as we have seen, generally referable to the immediate results or more remote vestiges of inflammatory action. On this head we shall add nothing to what has already been said in the last section, and refer the reader particularly to the facts there accumulated, and the concluding remarks upon them.

2. The relations of madness to other diseases, which are known to be connected with increased vascular action, or at least with increased fulness in the vessels of the brain, tend to support the same inference. The connection of apoplexy and paralysis, of epilepsy and of other cerebral diseases, with madness, has been pointed out by medical writers. These diseases are occasionally converted into each other, or mutually succeed each other, and undergo alternations. They display such a relation as leads us to believe that the proximate causes or the morbid changes on which the symptoms immediately depend, are in all analogous. Therefore, as some of the class, apoplexy for instance, and paralysis, are connected with vascular fulness in the brain, it is hence probable that a state not far removed from this, and at least likely, under the influence of slight causes, to pass into it, gives rise to the phenomena of madness.

The metastasis of inflammatory diseases from other parts of the body, among which is included the recession of cutaneous eruptions, is well known to be followed not unfrequently by the appearance of maniacal symptoms. Suppressions of catamenia and other discharges, giving rise to similar diseases, strongly confirm the same pathological principles.

3. The causes in general which excite madness bring us to the same conclusion. These are principally of a description likely to give rise either to inflammation in the brain, or to a full and distended state in the vessels of that organ. Exposure to severe heat or cold, insolation, concussion or other injuries of the head, intoxication, and generally excess in the use of stimuli, great mental excitement, are all of this class; the condition of the brain, which it is the tendency of these agents to promote, is either inflammation, or something bordering upon it.

These different considerations concur in rendering it probable that the actual condition of the brain which immediately gives rise to the phenomena of madness, is in general one of high vascular excitement or turgescence, a state which, if it does not really constitute inflammation, is at least closely bordering upon it, and so liable to pass into it, that all the usual consequences of inflammation in many instances arise from it.

But though we may be correct in drawing this inference as a general one, there are great difficulties to be overcome, and much remains to be proved, before we can be authorized to insist upon it as universally applicable. The phenomena of mental disease are so various, and even so diverse, that they may be thought, not improbably, to arise from very different states of the system. There are instances of mental disease conjoined with so much atony and debility, subsidence of vascular action, coldness of surface, and diminished secretions, as to indicate a very different state from that of inflammation. Anatomical researches display in these instances a pale discoloration of the brain, with abundance of serous fluid, softenings of substance, and other phenomena of a similar description. Here we trace a state different from inflammation, though perhaps its remote consequence.

Are there not, likewise, cases in which we are scarcely authorized to conclude that any disease of the brain has ever existed? Instances of moral insanity, in which obliquity of character exists through life, and scarcely ever amounts to aberration of intellect, and some cases of monomania, in which slight and transient hallucinations supervene upon moral obliquities of the same description, and appear at intervals, cannot perhaps be referred with any degree of probability to an active state of disease in the encephalon.

It is probable, on the whole, that such exceptions bear a small proportion to the number of cases to which the preceding remarks on the pathology of madness are applicable.

If these remarks are well founded, they lead at least to one practical indication for the general treatment of madness. In proceeding with the medical treatment of maniacal diseases, we shall do well to bear constantly in mind the probable condition of the brain, and to direct our practice more or less with a reference to it.

Yet we must not omit to observe that the physician who proceeds to treat cases of madness as instances simply of inflammation in the brain, and who expects to cure it at once, like any other local inflammatory disease, by the direct operation of antiphlogistic means, will very often find himself greatly disappointed. He will meet with many cases in which no perceptible benefit arises from bleeding, evacuations of all kinds whether general or locally applied, and combined with the whole series of remedies supposed to be required by the

existence of organic inflammation. Many patients will sink under such a course of treatment if carried on incautiously: it will leave the disease undiminished, and exhaust the powers of life. This depends, perhaps, on the influence of diseased states in other structures and organs, or on disordered functions of other parts which are complicated with, and in some instances give rise to, the disturbances existing in the brain. Inflammatory excitement is a part of the disease, but does not entirely constitute it, even in so far as the brain is concerned.

Perhaps we may venture on the assertion, that there are few instances of madness in which the practical indication arising from the view which we have taken of the pathology of this disease will not be found applicable during some periods of the case, though in many its application is very limited. The degrees in which it is admissible are very various.

In recent cases of mania, properly so termed, and of incoherent insanity, particularly in young and plethoric subjects, and where the disease has made its attack suddenly, and is accompanied with signs of considerable vascular excitement, much may be hoped from the antiphlogistic treatment, at least from certain parts of it judiciously modified. We shall now consider the different means of which it consists, and advert to the opinions of some of the most eminent practical writers with respect to their use in cases of insanity.

1. *Of Bleeding.*—Cullen recommends bleeding in the early stage of madness. He says that it has been common to employ this remedy in all cases of recent mania, and, as he thinks, with advantage. He observes that when the disease has subsisted for some time, he has seldom found bloodletting to be of service. "It is," he says, "a proper and even a necessary remedy in those instances of madness in which there is fulness and frequency of pulse, and when marks are observed of increased impetus in the vessels of the head." He prefers bleeding from the arm, while the patient remains in somewhat of an erect posture, and bringing on a degree of deliquium, which, he says, is a pretty certain mark of diminished fulness and tension in the vessels of the encephalon.

Pinel, whose authority could not fail to produce an impression, is in this respect decidedly opposed to Cullen. He considers the signs of vascular plethora in the head, or of determination of the blood thither, as very deceptive; and although he allows bleeding to be in some instances capable of averting attacks of recurrent madness when they are anticipated, he carefully abstains from the use of the lancet after the disease has actually broken out. Care is always taken, he says, to question the relatives of patients admitted into the hospital over which he presided, whether bleeding has been practised, and if so, what were its results. "The reply always proves that the state of the patient has changed for the worse immediately after bleeding." Pinel held very firmly the opinion that bleeding, even in maniacal cases which are accompanied by circumstances supposed to indicate plethora and local determination to the head, tends to retard recovery, to render it more doubtful. He is even persuaded that bleeding gives to the disease a tendency to degenerate into dementia or idiotism. The facts, however, which this distinguished author adduces as proofs of his opinion, afford, as M. Foville has remarked, but very equivocal evidence. "Two girls," he says, "nearly of the same age and temperament, were admitted into the hospital (the Salpêtrière) on the same day: one of them, who had not been bled, was cured in the space of two months; the other had undergone a copious bleeding. She sank into a state of idiotism, or rather of dementia, and did not recover the faculty of speech till the fifth month. Her perfect restoration took place at the end of the ninth month." Now, as most authors fix the mean duration of madness at the period of several months, and some at more than a year, this case of recovery at the end of the ninth month cannot afford a strong condemnation of the practice pursued. Another case, which the same author has adduced as affording evidence against bleeding, is not more conclusive in respect to the influence of remedies on the ultimate event of the disease. Yet the opinion of such a writer, founded as it was, at least by himself supposed to have been, on extensive observation, ought not to be entirely disregarded because he happened to select but dubious illustrations. If bleeding occasions a state of collapse in the system, and is carried beyond what is necessary to reduce an over-excitement, a fatuitous dejection of mind is likely, in some cases, to be the result.

M. Esquirol coincides with Pinel in the opinion that the diseased state on which mental derangement depends, is sometimes changed for the worse by bleeding. He says that he has seen madness increased after an abundant flow of the catamenia, and likewise after one, two, or three bloodlettings. In such cases melancholy dejection has passed into furious madness. Yet M. Esquirol approves of moderate bleeding in plethoric cases, and where some habitual sanguineous evacuation has been suppressed. He has often, with advantage, applied leeches behind the head or to the temples of patients who are subject to sudden determinations of blood towards the head. His favourite remedies in such cases were the use of a few leeches at a time, repeated as often as necessary, and cold applications to the head.

To outweigh the authority of those writers who either condemn the practice of bleeding in madness, or allow of its adoption in so sparing a degree, strong evidence is requisite, but such evidence we possess.

Dr. Haslam says that bleeding is the most beneficial remedy that has been employed in madness, and that it is equally beneficial in melancholic as in maniacal cases. He limits its use to recent cases and plethoric habits, and directs it to be performed by the application of six or eight cupping-glasses to the shaven scalp. The quantity of blood to be taken must depend on circumstances. "From eight to sixteen ounces may be drawn, and the operation repeated as circumstances may require." When a stupid state has succeeded to one of high excitement, Dr. Haslam considers bleeding as contra-indicated.

But Dr. Rush is the most strenuous advocate for bleeding in maniacal cases. He lays the greatest stress on this remedy, and has perhaps carried its use to a greater extent than any other medical

practitioner of high repute. The arguments which he has given in support of the practice of large depletion in madness are the following:—1. The force and frequency of the pulse, the sleepless and agitated state of maniacal patients. 2. The appetite being unimpaired in lunatics, and sometimes even stronger than usual, a plethoric state of the vessels easily arises in such habits. 3. The importance of the diseased organ, the delicate structure of the brain, which prevents it from long supporting morbid action without being exposed to the danger of permanent disorganization. This danger, he says, is much increased by the want of sleep, the cries and exclamations, and the constant agitation of mad persons. 4. The want of any natural channel of discharge from the brain, by which the ordinary results of inflammation might be averted or got rid of, in that way by which serous discharges in other parts relieve the inflammatory state. 5. The accidental cures which have followed the loss of a large quantity of blood. Dr. Rush has seen several lunatics who had attempted self-destruction by cutting their throats, or opening the great vessels, cured by the abundant hemorrhages which have followed these attempts. 6. Lastly, he says that bleeding is indicated by the extraordinary success which has resulted from its use in the United States, and particularly at the hospital for lunatics in Pennsylvania.

Dr. Rush advises large bleeding at the first attack of mania. If the patient bears it without syncope, he ought to lose, according to this physician, from twenty to forty ounces of blood. If possible, it should be taken from him while standing erect. Free bloodlettings practised early in the disease have, as he says, a surprising effect in calming the patient, and in many instances are sufficient for the cure unaided by any other remedies. In most cases, however, bleeding from the arm is to be followed by the application of leeches or cupping-glasses to the head or nape of the neck, by low diet, antiphlogistic remedies, refrigerants applied to the head, and the use of warm or tepid baths.

Dr. Rush was of opinion that the evacuation of blood ought to be carried to a greater extent in madness than in any other acute disease whatever. From a patient, sixty-eight years of age, he caused two hundred ounces of blood to be drawn in less than two months. Another patient of Dr. Rush lost four hundred and seventy ounces by forty-seven bleedings in the course of seven months.

We shall conclude this survey of the conflicting opinions of practical writers on the expediency of bleeding in madness, by the following observations of M. Foville, which are deserving of the most attentive consideration, and which in our opinion place the subject in the true point of view. He says, "Without ever having pushed the employment of this remedy so far as Rush and Joseph Frank, I confess that it appears to me to be one of those on the efficacy of which the greatest reliance may be placed. MM. Pinel and Esquirol have proved that the 'expectant method,' assisted by a few simple rules, and a moral treatment wisely directed, have succeeded in a great many cases; but although it is better to confine ourselves to the use of simple means, patiently continued, than to employ unadvisedly the method of interference, I believe that the physician devoted to the study of pathological anatomy can draw from the results which it furnishes, compared with the observation of symptoms, valuable therapeutic inductions; that he may place reliance on their efficacy, and recommend them with confidence when experience shall have demonstrated their good effects. Are not the anatomical characters which so constantly present themselves in acute cases, and the adhesions which are so frequent in chronic ones, evident proofs of inflammation? And hence, are we not authorized to hope for advantages from the use of antiphlogistic means?

"If it be added," says M. Foville, "that in several hundred lunatics, whose bodies my situation for nearly ten years has given me an opportunity of examining, I have never found adhesions in acute cases, while they have been very common in chronic cases; if, with these facts, the results related in the works of MM. Bayle and Calmeil are compared, we may conclude, on seeing these adhesions so frequent in chronic cases, that they are incompatible with the regular exercise of an organ so delicate as the brain, and consequently incompatible with the return of reason. Hence we ought, in every acute case, to choose the most active means, in order to prevent this melancholy termination of the cerebral disease.

"Such are some of the reasons which have led me to agree with several physicians who have been placed in circumstances favourable for making observations, that bleedings ought not to be entirely proscribed in the treatment of mental diseases. In the greatest number of cases of recent insanity which have been placed under my care, I have employed evacuations of blood, local or general, rare or frequent, abundant or in moderation, according to the strength of the patient, and the state of the pulse, the redness of the eyes, the heat of the head, the agitation and want of sleep. I have always preferred general bleeding, when there existed a state of plethora, which the force and frequency of the pulse evinced. In opposite circumstances, leeches on the neck, the temples, behind the ears, cupping upon the same part, and upon the shaved head, have produced decided benefit. Local bleeding having appeared to me to produce a marked effect upon the brain, I have often prescribed it at the same time with a general bleeding in the case where the intensity of the general phenomena has imperiously demanded the latter; but I have never rested exclusively upon the efficacy of sanguineous evacuations, although in many cases I have seen all the morbid symptoms disappear, as if by enchantment, under their use.

"I have under my care several patients subject for a number of years to attacks of intermittent madness, which, left to nature, would last three or four months, or longer.

"During three years, that is, since they have been confided to my care, they have not experienced a single attack of a month's duration. Often in the space of five or six days all the symptoms have been dissipated. General or local bleedings proportioned to the intensity of the symptoms, warm baths with cold applications to the head at

the same time, are the means by which I have constantly averted the attack.

"I have several times prevented the return of these attacks by employing the same treatment, as soon as the redness of the eyes, the heat of the head, and wakefulness manifested themselves, even when there had been no delirium."

The writer of the present article having superintended during nearly twenty years a receptacle for maniacal paupers, has possessed adequate opportunity of forming an opinion on the ground of his own experience as to the efficacy of different remedies, and among other practical questions with reference to the treatment of insanity, as to the extent to which bloodletting is advisable in this disease. The results of his own observation lead him to doubt the propriety of the copious bloodlettings of which Dr. Rush is the advocate. He believes the cases of madness to be comparatively few, which can be cured at once by large depletions, and is sure that considerable danger to the existence of the patient would often be incurred if such a practice were generally pursued. At the same time he is equally convinced of the propriety of moderate detractions of blood, as advised by Cullen, Haslam, and Foville. This remedy ought by no means to be neglected in cases of madness which have come on rather suddenly and with acute symptoms, unless some circumstance in the age, habit, or temporary condition of the patient, renders it unsafe. It is especially called for in young and in plethoric subjects; when the disease is one of great excitement; when there is constant agitation and want of sleep, and in such cases it should be adopted before these causes have induced exhaustion and collapse; when there are marks of determination to the head, such as full and throbbing carotids and temporal arteries, redness of the face and conjunctiva, heat of the scalp, a contracted pupil, intolerance of light or of sound, headach, vertigo, startings, agitations, or convulsions. We are not to look for an aggregate of these symptoms before we prescribe bleeding, but more or fewer of them often occur to direct our proceedings. Less frequently we find the still stronger indications of which even M. Esquirol allows the force as pointing out the necessity of bleeding. We allude to the circumstance that the disease has arisen from the sudden suppression of catamenia or of some morbid but, perhaps, also salutary discharge, from the disappearance of eruptions, or from the operation of powerfully exciting causes. Among these is the abuse of stimulating liquors. Madness, which is the effect of intoxication, requires antiphlogistic remedies, and bleeding cannot be dispensed with; but care must be taken not to carry depletion too far in cases arising from this cause which assume in some degree the character of delirium tremens. We have reason to believe that patients labouring under delirium tremens have been killed almost instanter by large bleedings, which had been ordered by practitioners who were unaware of the nature of the case. This, however, is a form of disease easily distinguishable from ordinary madness resulting from intoxication. It is frequently advisable to bleed once or twice from the arm to the extent of fourteen or sixteen ounces, and afterwards, if the indicatory symptoms continue, to apply cupping-glasses to the scalp, after it has been shaved, and repeat this operation or the application of leeches as often as the degree of excitement and signs of vascular fulness, the circumstances of the patient otherwise admitting, seem to require.

Many practical writers have insisted on the necessity of bleeding in the early stage of madness, without adverting to the important advantages which are to be derived from the same remedy in the after periods of the disease. These, however, are highly important. The practice of bleeding to a small extent, either from the arm, or, what is commonly preferable, by cupping-glasses applied to the scalp or the nape of the neck, and repeating the operation in some instances periodically when the tenor of symptoms has been nearly uniform, or occasionally when the patient has been subject to fits of increased excitement, has appeared conducive to ultimate recovery in a great number of instances. When suppression of the catamenia or of hemorrhoidal evacuations has preceded the attack, cupping on the sacrum or the application of leeches to the hemorrhoidal vessels may perhaps best supply the defect of the natural or habitual method of relief.

The other resources, which are comprised under the antiphlogistic treatment of madness, will require a much less extensive consideration.

Shaving the head should always be done when there is much vascular excitement and heat about the scalp. By the coolness afforded on the removal of the hair, more benefit and a greater degree of tranquillization is often produced than is anticipated. Cutting the hair short is not sufficient: the head should be shaved once or twice a week.

Blisters, setons, caustics, irritants of various descriptions, have been applied to the head and the nape of the neck in cases of madness, as well as in other diseases of the brain.

While acute symptoms are present, with heat of the head and irritation of the general system, cold applications are preferable to blisters; but when these indications are not prominent, and when there is rather a tendency to stupor than excitement, blisters on the head are frequently of service. They have been applied in most cases to the nape of the neck with some advantage, particularly when, as it has often happened, the discharge which follows their application has been very considerable.

M. Esquirol has remarked that blisters, cuppings, and other irritating applications, are used successfully in cases which follow a metastasis; in monomania accompanied by stupor; in puerperal madness; and in dementia when not complicated with convulsions or paralysis.

Issues and setons in the neck have been often tried, but the general result of experience is not favourable to their use. They afford little benefit in maniacal cases. In dementia connected with paralytic affections, they are more likely to be of service than in mania attended with excitement. In the ordinary chronic state of madness, these remedies are found to be rather injurious than beneficial.

Irritating ointments have been applied in many instances, particularly since their use was strongly recommended by the late Dr. Jenner. Medical

practitioners have been generally disappointed in their expectation of benefit from this attempt. It is most likely to be successful, as hinted by M. Esquirol, in cases of metastasis.

[It may be borne in mind, however, as a remarkable fact, that in the Gloucester Lunatic Asylum, England, which is under the superintendence of Dr. Shute and Mr. Hitch, the use of the lancet, leeches, cupping-glasses, blisters, drastic purgatives, and the practice of shaving the head are totally proscribed, and yet recoveries take place in a large proportion, and no cases of sudden apoplexy or hemiplegia have occurred. The practice of making an incision through the scalp, over the sagittal suture, with the view of establishing steady counter-irritation, has been employed for some years past by Dr. C. Evans, physician to the Frankford Insane Asylum, near Philadelphia, in the treatment of chronic affections of the brain; and, it is said, with very satisfactory results. The actual cautery and the *Pommade ammoniacale* of Gondret have likewise been applied with advantage. (See COUNTER-IRRITATION.)]

Cold Water and Bathing.—Cold shower-baths, and affusions of cold water administered in various methods, have been extensively tried in maniacal diseases. Dr. Rush considered them to constitute a very important remedy, and recommended, in order to obtain the greatest advantage from them, that they should be repeated two or three times in a day. M. Esquirol used this remedy with advantage in some cases; he chiefly prescribed it for young subjects. M. Foville says that he was a witness to an almost immediate cure of a maniacal girl of delicate constitution and nervous temperament, who was subjected by M. Esquirol to the affusion of cold water at the degree fourteen of the centigrade thermometer. She was placed, with a garment covering her, in an empty bathing-tub, and water was poured in small quantities on her head till it covered her body, and shivering ensued. On a second application of this method, which was for some time resisted, it was followed by deep sleep, accompanied by copious sweating; and when the patient awoke, she was found to have recovered her reason.

The method of bathing adopted by M. Foville in the hospital under his management is free from the inconveniences and occasionally injurious results attendant on cold affusions. He places a cap or bonnet, containing ice and closely fitting, on the head of the patient, and keeps the body immersed in a warm-bath for two or three hours, and renews this proceeding twice or three times in a day, according to the intensity of symptoms. On adopting it, as he was accustomed to do at first, only once in a day, he found the tranquillity produced by it followed not unfrequently by increased agitation; but on repeating the bath, with the ice constantly applied to the head, he has frequently succeeded far beyond his expectation. It has been the apparent means of recovery in many acute cases, and has produced sleep and tranquillity in frequent instances of obstinate restlessness and agitation.

The use of the shower-bath is often followed by re-action, when the patient, if excitable, becomes violent. In old cases, attended with a disposition to congestion of blood in the head, its use is precluded by the danger of producing paralysis. It is chiefly serviceable in young subjects; when the constitution is relaxed, and when it is predisposed to hysteric affections.

Applications of ice, or, when more convenient, of cold water, are very generally serviceable in cases attended with heat of the head and irritability.

Warm or tepid bathing has been found advantageous in the treatment of madness under a variety of circumstances. A cold state of the skin, languor of the general circulation, indicated by coldness of the extremities, a tendency to chronic eruptions, are among the phenomena which suggest its adoption. Sometimes it produces sleep after long-continued agitation. If the degree of heat be not such as to produce too much vascular excitement, it is generally an useful and safely applicable remedy.

Purgatives.—No fact in medical practice has been longer established than the utility of purgatives in madness; witness the fame of Anticyra and hellebore. To confirm a maxim so well supported by the result of constant experience, it seems almost superfluous to adduce pathological facts. It is not, however, difficult to find this species of evidence in its favour. Many authors have remarked that spontaneous cure of madness has resulted from a supervening diarrhœa, in which the intestines have discharged in great quantities a variety of morbid secretions.

M. Esquirol has well observed that purgative medicines ought not to be used indiscriminately in all cases of madness, and that they are injurious when the mucous membrane of the intestinal canal is in a diseased state. This is the case in many instances of insanity. We shall, under another indication for medical treatment, consider the method of practice which is advisable in different states of intestinal irritation, as they occur in madness. At present it will be sufficient to observe that, unless any signs of disease exist in the structure of the alimentary canal, such as inflammation or ulceration of the mucous coat of the intestines, the use of purgative medicines is one of the most important and generally available means for the cure of maniacal patients. The mildest cathartics are preferable to others in most instances, because their use can be long continued without injury to the structures on which they immediately act. The neutral salts, infusion of senna, rhubarb, jalap, castor oil, are in the majority of cases sufficiently powerful, and may be used daily or frequently according to circumstances. When there is decided tendency to constipation or the alvine evacuations are morbid, calomel scammony, colocynth, or croton oil, may be added due attention being paid to the cautionary circumstance above pointed out.

Emetics.—Emetics have been strongly recommended by some practical writers. M. Esquirol says that he has found them useful in most cases of melancholy accompanied by a torpid state of the system. Dr. Rush considered them to be chiefly indicated in hypochondriasis, or lowness of spirits connected with dyspeptic disease. Haslam confirms their utility in cases attended with disorder of the stomach, merely with a view to the relief of that particular symptom, but he de-

clares that, "after the administration of *many thousand* emetics to persons who were insane, *but otherwise in good health*, he never saw any benefit derived from their use." "Perhaps no one," he says, "has enjoyed a fairer opportunity of witnessing the effects of remedies for insane persons than myself; and when emetics are employed in Bethlem Hospital, they have the best chance of effecting all the relief they are competent to afford, as they are given by themselves, without the intervention of other medicines; and this course of emetics usually continues six weeks." "It has been for many years the practice of Bethlem Hospital to administer to the curable patients four or five emetics in the spring of the year; but on consulting my book of cases, I have not found that such patients have been particularly benefited by the use of this remedy. When the tartarized antimony given with this intention operated as a purgative, it generally produced beneficial effects." The most strenuous advocate, in late times, for emetics in madness is Dr. Cox, whose work on that disease contains many excellent practical observations. This author goes so far as to say, that, "in almost every species and degree of maniacal complaints, from the slightest aberration of intellect that accompanies hypochondriasis, to the extreme of mania furibunda, emetics have proved a most valuable and efficacious remedy." Dr. Wake, physician to the York Lunatic Asylum, has assured the writer of this article, that, after extensive experience in the use of different remedies on the patients of that hospital, he has found no other class of remedies so frequently efficacious as emetics.

The use of emetics in madness requires caution. Dr. Haslam says, that, "in many instances, and in some where bloodletting had been previously employed, paralytic affections have within a few hours supervened on the exhibition of an emetic, more especially where the patient has been of a full habit, and has had the appearance of an increased determination to the head." As it is well established that lunatics are very subject to attacks of apoplexy and paralysis, this circumstance ought always to be taken into consideration in the prescribing of emetics to maniacal patients. The use of medicines of this class is precluded by the signs of a plethoric habit and cerebral congestion; but, as MM. Esquirol and Foville have well observed, they are likely to be of service, and this probability is confirmed by ample experience, in cases of melancholy or hypochondriacal dejection attended with stupor, and where the languid state of the functions, both animal and physical, appears to require the use of remedies which are fitted to excite new actions, and to stimulate the secretions of the abdominal viscera. It may be added that emetics are sometimes useful during a state of furious excitement, and produce calmness and a mitigation of violence. Sometimes under these circumstances their exhibition is followed by a restoration of sleep and tranquillity.

Maniacal patients often require large doses of tartarised antimony, as from six to ten grains, before vomiting is excited; and this is especially the case when the remedy is given during a paroxysm of violent excitement. It is, however, better to begin with moderate doses, and to combine ipecacuanha with the preparation of antimony.

The use of antimony in nauseating doses is always safe, and very frequently beneficial in controlling maniacal excitement and the febrile state of the system which accompanies it.

Rotation.—The use of a rotary swing, which occasions vertigo and nausea, and if continued a sufficient time, brings on vomiting with some degree of faintness, was suggested, chiefly from a theoretical notion, by Dr. Darwin. The beneficial effects of this remedy have been supported on the ground of experience by Dr. Cox. Some writers have ridiculed the idea of attempting such a remedy, and others have thought it difficult to imagine on what principle it can be of any service; but those practitioners who have put the proposal to the test of experiment have, if we are not mistaken, in most instances been convinced of its utility. Among these may be mentioned Dr. Wake of York, who has assured us that he has long considered the rotatory swing as a remedy of great efficacy. It was used by Dr. Cox in cases of violent maniacal excitement, and proved a powerful sedative. The nausea and sickness induced were found to quiet the patient and put a speedy termination to the paroxysm. It was not requisite in all cases to bring on vomiting. Quiet sleep often followed the use of this remedy.

The rotatory swing is also useful as a means of moral restraint. The effects are so disagreeable that the threat of repeating its use has a salutary influence upon turbulent and intractable patients.

2. *Second Indication.*—The principle of medical treatment hitherto considered, which has respect to the physical condition of the brain in cases of maniacal disease, is chiefly applicable to the acute stage and early period of its duration. The pathological fact on which it in part is founded, may be usefully borne in mind in the subsequent progress of the complaint, and acted upon more or less when circumstances allow or require it; but it cannot, when the disorder has become confirmed, be the chief guide of the practitioner. The marks of determination to the head have generally, under such circumstances, in a great measure subsided. In these instances inflammatory action in the brain has probably given way to a state of relaxation bordering on serous effusion, or to other changes which imply rather the consequences than the existence of increased vascular action.

The second indication for the medical treatment of insanity, which has relation chiefly to the more advanced period and chronic aspect of such disease, is to restore and maintain, as far as it can be done, a healthy condition of the physical or natural functions, to obviate or remove disorders in other parts of the system, which may be connected or coincident with the diseased condition of the brain.

We have already observed that in a great proportion of maniacal cases there are symptoms of disturbance in the natural functions, and that diseases of the thoracic and abdominal viscera coexist with that morbid state of the brain on which madness immediately depends;—that the former

are in fact often the immediate causes of death. The relation in which these diseases stand to the cerebral disorder may be doubtful in many instances; in some it is the relation of cause, in others that of effect: even in the last instance there is a reaction of the secondary upon the primary parts in the series of morbid changes, and the original disease is aggravated by its complication with an accessory one. By relieving the latter we obtain a proportional mitigation of the former. It is indeed a fact that many lunaties have been cured by a course of remedies adapted to the restoration of their general health. The writer of this article has often seen persons who had laboured for some months, or even years, under mental derangement, brought from poor-houses in the country, or from their private dwellings, in a state of emaciation and squalid wretchedness, suffering under various disorders which had become complicated with insanity, or had in some instances preceded it. These persons have been placed under medical treatment; care has been taken to relieve the symptoms of visceral disorder, to restore the functions to a healthy state, to afford them good and nutritious diet, and to remove complaints which occurred from time to time by occasional remedies. In many cases of this description, as the general health improved, the mental disorder has gradually lessened, and has finally disappeared. In the course of four, five, or six months from the period of their coming under medical treatment, very many patients of this description have been restored to their usual state of health, and to the exercise of their customary occupations, after having undergone the operation of few remedies except such as are adapted to the indication or principle of practice now pointed out.

The mode of treatment required in following this indication must vary according to the state of the constitution and the modifications of disease which particular cases may present.

In examples of madness complicated with intestinal disorder, care must be taken to relieve the latter by the various remedies and modes of diet and regimen which the disorder of the intestinal canal and its functions requires. A torpid state of bowels must be overcome by the use of mild aperients, continued daily, or given occasionally according to circumstances. When constipation has given way to diarrhœa, with tenderness, abdominal distension, with or without occasional symptoms of dysentery, with emaciation, coldness of the skin, general debility, a disposition to eruptions resembling those of scurvy or purpura, the cure can only be promoted by a careful attention to a variety of particulars. The action of the bowels should be restrained by absorbent medicines, combined with slight opiates and mercurial alteratives. The use of the warm bath, warm clothing, and a warm atmosphere, a mild and nutritious diet, should be enjoined at the same time. Bitters, vegetable tonics, and aromatics may be given to support the strength of the stomach and promote digestion: a liberal allowance of animal food, and sometimes malt liquors, and even a little wine are used with advantage in cases of debility and exhaustion when the digestive powers will bear their use.

When the actions of the intestinal canal are irregular in chronic cases of madness, without giving rise to so great a degree of disease as in the instances above indicated, a healthy state of their function is sufficiently promoted by giving mild aperients, with bitter and neutral salts, two or three times in a week, and occasional doses of calomel.

When madness has been the result of, or has been accompanied by, diminution or loss of any other natural function or habitual process, an effort should be made to restore it. If we were possessed of any certain emmenagogue, it is highly probable that its successful application would in many cases promote the cure of maniacal diseases connected with the suppression of the catamenia. When habitual discharges from the hemorrhoidal veins have been coerced, or have ceased spontaneously, derangement of the health has ensued similar to that occasioned by uterine suppressions. The want of this latter process seems to be more easily supplied by the powers of art than that of the uterine function. M. Foville has mentioned a case which occurred to M. Esquirol, in which paralysis became complicated with madness in consequence of the suppression of an habitual hemorrhoidal discharge. The application of a single leech to the hemorrhoidal veins every day during a month was followed by a restoration of the flux, and the patient was cured of his complaint.

Attempts to restore the catamenia when defective in maniacal patients, as they very frequently are, seldom produce in a speedy manner the desired result. If any effort is perceptible at particular times to set up the periodical discharge, it should be promoted by small bleedings; by the application of leeches to the inguinal region of the thighs, or by cupping at the loins, together with the use of the hip-bath, pediluvium, general warmth of clothing and atmosphere, warm drinks, with doses of castor, camphor, and other odorous stimulants. At other times aloë, rhubarb, and aromatic bitters should be given daily by way of preparation.

Digitalis has been reckoned by some practitioners, particularly in Germany, as almost a specific in maniacal cases. Dr. Cox speaks favourably of its effects. By M. Foville its use is very judiciously limited to those instances in which disorder of the brain is coincident with, and, as he supposes, dependent upon disease, or at least increased action of the heart, and particularly increased fulness and pulsation of the carotid and temporal arteries.

Opium and narcotics are *generally* injurious in madness. Their use is condemned by most practical writers. Occasionally, however, opium has been of decided benefit. Dr. Hodgkin has witnessed two cases of madness with a strong propensity to suicide, in both of which a strong dose of opium procured sound sleep, followed by a restoration of health. The use of opium requires great caution in maniacal diseases. No precise rules are determined by which we can judge of the propriety of its use.

[In large doses, it is strongly advised by some practitioners, as by Drs. Brigham and Woodward. The writer has administered it in the long protracted sleeplessness of insanity, and often with

decided benefit; but it requires to be given in large doses, at least two and a half or three grains, in the form of pill; and the dose may be repeated should it be necessary.]

The use of mercury has been highly recommended in madness by several writers, and particularly by Dr. Rush. Mercury is by no means a general remedy for maniacal diseases; but in cases of torpor, with suppression or a very scanty state of any of the secretions, mercury is frequently employed with great advantage. It should be used in mild alterative doses, and discontinued as soon as the gums become slightly affected.

Attention to diet and regimen is fully as important for the fulfilment of the last-mentioned indication as any remedy whatever. In exhausted subjects, as before hinted, great advantage is obtained from the use of a liberal diet. A plentiful allowance of animal food of the most wholesome and digestible kind, with malt liquor, and in some instances a small portion of wine, is required. The adoption of a liberal diet is not only free in such cases from any exciting or too stimulant influence, but even appears to calm the irritation which previously existed. But no rule respecting diet can be laid down that must not be subject to modification in particular circumstances, and according to the peculiarity of the case and the state of the constitution.

Fresh air and exercise, for those patients who are in a condition that renders them fit for it, are among the most important restorative means.—Every asylum for the reception of lunatics ought to be provided with the means of affording regular employment in the open air to all the patients who are able to undertake it. Gardening and various agricultural works should as much as possible occupy their time at stated periods of the day, and by system and judicious management a great majority among the inmates of these receptacles may be brought into the habit of devoting themselves mechanically to such employments. M. Esquirol remarks that the best effects have resulted from the employment of these methods. They are followed with the greatest advantage in several lunatic asylums, both public and private, in different parts of England.

Of the moral treatment of Insanity.—We now proceed to the second division of the subject under consideration, viz. to the moral treatment of insanity.

The moral treatment of this disease has by many writers been made to include a variety of methods proposed with the hope of inducing, by an unexpected and powerful influence on the feelings of deranged persons, a salutary change in the state of their minds. These are either motives addressed to their passions, or a variety of ingenious schemes or stratagems for convincing them of the falsity of their hallucinations, and surprising them into a recognition of their erroneous impressions. It has been proposed to indulge the illusions of the insane to a certain degree in order to overcome their false notions by striking and undeniable proofs. We are told that a lunatic who fancied that he had a serpent in his stomach, was cured by giving him an emetic, and adroitly producing a reptile as if it had been thrown up during the operation of the medicine. Even such writers as M. Pinel and M. Esquirol, otherwise so enlightened and so judicious, appear to lay some stress on attempts of this description. The latter had a patient who fancied that she had a little animal in her head: her physician encouraged the idea, and proposed an operation; an incision was made on the scalp, and an insect produced: the patient was immediately cured. A lunatic mentioned by the same writer refused to eat; he had made a vow, and was bound in honour to abstain from food. After many days employed in the attempt to persuade him of his mistake, a pretended order was brought, signed by his sovereign, which commanded him to break through his resolution, and promised him a guarantee against any reproach on that account: after a moral struggle of some hours, he gave way with reluctance, took food, and was restored. Another individual, who had become insane in consequence of the political events of 1813, was informed of the revolution which occurred in the following year. He refused to believe. M. Esquirol led him into the midst of the foreign troops which surrounded Paris. He was convinced, and almost immediately cured.

It is barely within the sphere of possibility that a conjuncture may occur in the treatment of an insane person, when an attempt may be advisable to destroy his hallucination by some practical and striking proof; but, generally, attempts to convince lunatics that their impressions are false, and that they labour under mental disease, either by reasoning or by any contrivances, are abortive, if not injurious. The moral treatment which such cases actually require is of a very different kind.

The most important question which relates to the moral treatment of the insane turns upon the propriety of secluding them, and separating them from their families and from society. This is a subject which of late has excited much attention and serious consideration, both among medical practitioners and other persons in England. It has likewise been examined in every point of view by writers of just celebrity on the continent; M. Esquirol and M. Georget in particular have considered this subject in all its bearings, and have expressed their sentiments upon it with great perspicuity and soundness of judgment. We shall avoid all suspicion of prejudice or erroneous bias by citing the observations of these writers, whose authority will carry greater weight than that of most other individuals, removed as they have been from the influence of circumstances which have given rise to controversy and unreasonable varieties of opinion.

"The first question," says M. Esquirol, "that presents itself in connection with the moral treatment of lunatics, relates to their separation. Ought every insane person to be withdrawn from his accustomed habits, from his usual manner of living, separated from the persons with whom he habitually lives, to be removed into a place which is unknown to him, and confided to the care of strangers? All physicians, English, French, and German, agree upon the necessity and utility of separation. Willis, to whom we have so long and with so much advantage resorted in England to obtain a cure in cases of insanity, has remarked that strangers were restored much more often than the English. We can make a parallel observation

in France. Cures are more frequent among the invalids who come to Paris to be treated there, than among those who reside in the capital. The latter have not been sufficiently isolated.

"The first effect of separation is to produce new sensations, by presenting new objects, and breaking the train of ideas which has laid hold on the mind; these new objects strike, arrest, and excite the attention of the lunatic, and he becomes more accessible to advice which may be the means of restoring him to reason. Thus the first moment in which a maniac is separated from his friends is always followed by a remission of the complaint, which is important for his physician, who, then finding the patient without prepossession, can more easily acquire his confidence.

"It is principally upon the disorder of the moral affections that the necessity of separation depends.

"The disturbed state, the exaltation of ideas of the insane patient, puts him in contradiction not only with those who live with him but even with himself. He persuades himself that his friends are determined to oppose him, because they do not agree with his excesses and extravagances. Not understanding what is said to him, he is impatient; generally he misinterprets the words that are addressed to him; proofs of the most tender affection are taken for reproaches, or for enigmas that he cannot understand; the most anxious cares are only intended to vex him; his heart cherishes only sentiments of defiance; he becomes timid and gloomy; he fears every one who approaches him; his suspicions extend to persons who had been most dear to him. The conviction that every person is intent upon opposing him, defaming him, rendering him miserable, destroying and ruining him, puts a completing stroke to this moral perversion." Thence arises that "symptomatic suspicion which increases under indispensable contradictions, which augments in strength as the intellectual faculties weaken, and which is painted so strongly upon the physiognomy of all insane patients."

"With these moral dispositions, if you leave an insane person in the midst of his family, the affectionate son, whose happiness consists in the society of his father, will soon desert the paternal roof. The despairing lover believes that he can, by his councils, bring back the wandering reason of her to whom he is devoted; he has the misfortune only to render the wound still deeper. The object of his affection soon sees in him only a perfidious traitor, who affects such eager anxiety the more easily to betray her. The tender and sincere friend hopes by affectionate cares to restore that sensibility and that reason which have been the source of his attachment and happiness. In a short time he will find himself included in the general proscription, and his cares will only appear to the afflicted person proofs that he has been corrupted by enemies. What hope can we entertain if we do not immediately change the situation of these unfortunate persons, who are so strongly prepossessed? And who has not felt the difference that there is in being deceived, opposed, and betrayed by our nearest relations and friends, and by individuals who are altogether strangers and indifferent to us? Another unhappy person becomes, all at once, lord of the world, dictates his sovereign commands to all that surround him; he persuades himself that he is blindly obeyed by all those who have been accustomed to yield to his will through respect or affection. His wife, his children, his friends, his servants, are his subjects; they are all obedient, for how dare they be otherwise? He is in his own territory; his commands are despotic; he is ready to punish with the greatest severity whoever shall dare to make the least remonstrance. What he requires may be impossible—it is of no consequence: should the commands of the potentates of the earth meet with invincible obstacles? The affliction of his family, the chagrin of his friends, the anxiety of all, their deference to his will and caprices, the repugnance that each evinces to oppose him from the fear of exasperating his fury,—all contribute to confirm him in his silent possession of power and dominion. Withdraw him from his pretensions, transport him far from his house, from his empire,—removed from his subjects, surrounded by new scenes, he will collect his ideas, direct his attention to himself, and place himself on an equality with his companions.

"Very often the cause of mental derangement is to be found in domestic causes. The malady takes its rise from chagrins, from family dissensions, from reverses of fortune, from privations, &c.; and the presence of relations and friends increases the evil, often without their suspecting that they are the first cause of it. Sometimes an excess of tenderness seizes the patient; a husband persuades himself that he cannot make his wife happy; he forms the resolution of flying from her, and threatens to put an end to his existence, since it would be the only means of securing her happiness. Her tears, her melancholy countenance, are so many new reasons for persuading this unfortunate person that he can do nothing better than commit suicide.

"Sometimes the first commotion given to the moral and intellectual faculties has arisen in the home of the insane person, in the midst of his relations and friends. All these external circumstances being associated with the first attack and the disorder which followed, will often contribute to keep alive and foster the hallucination,—a phenomenon which easily explains itself, since ideas recur simultaneously with certain impressions, when these impressions and ideas have often been associated, or even when they have been connected, only once, but with remarkable force and energy. It is generally remarked that insane people feel an aversion towards certain individuals, without the possibility of diverting them from this feeling. The object of their hatred is almost invariably the person who before the attack possessed their tenderest affection; hence it is that they are so indifferent to their relations, and oftentimes so dangerous; while, on the other hand, strangers are agreeable to them. The presence of strangers suspends the delirium of the insane, either by the influence of new impressions, which is always useful, or from a secret feeling of self-love, which induces lunatics to conceal their state of mind. I have seen patients appear quite calm before their physician and strangers, while they were at the same time abusing their relations or their friends in an under voice.

"Such are the obstacles and inconveniences that present themselves when patients are put under medical treatment, if they continue to live with their families; and such are the advantages that will accrue from their being placed in a house appropriated to their treatment, where they are surrounded by new circumstances and confided to the care of strangers.

"Under what circumstances ought they to be confined? We have already said that they ought to be placed in a house appropriated for the treatment of insane persons. We prefer such a house to a private one, where patients may be confined at a great expense. Such partial separations rarely succeed: they possess many of the inconveniences which it is desired to avoid in leaving patients in their own habitations, and they present very few of the advantages of a house destined to receive a number of individuals. The strongest objection against separation or the placing patients in a lunatic asylum, arises from the distress which it is feared the patient will suffer when he observes that he is surrounded by companions in affliction. I reply that, generally, this does no injury to the patient, that it is not an obstacle to the cure, and that it oftentimes contributes to promote recovery. It leads maniacal persons to reflect upon their own state; and while ordinary objects make no impression upon them, they are diverted by the extravagances of their associates. The presence of their companions may serve as a text to the practitioner who wishes to act upon their imagination. The weariness of confinement, the desire of being at liberty, the wish of seeing their relations and friends, are so many means of drawing their attention outwardly: to be occupied with what passes around them, and in some manner to forget themselves, is a step towards recovery. However, there are cases where separation, as all other useful things, may be injurious to patients, when it is not modified with reference to the susceptibility of the individual, the character of his delirium, his passions, his habits, his manner of living. We ought never to lay down absolute rules in practice; the art consists in skilfully discriminating the circumstances which ought to modify general principles, whatever confirmation they may have derived from experience."

The preceding observations of M. Esquirol have been confirmed, and in some particulars more strongly stated, by the late M. Georget. This intelligent writer has remarked that all physicians who have habitually the care of lunatics have recommended the seclusion of these invalids, in almost every case, as the first condition, and one of the first means in their treatment. "Lunatics," he says, "ought to be separated from the objects which have excited their disease, or which foster or aggravate it; from relatives or servants whom they dislike, whom they pretend to command, and to whom they will never submit; from busybodies, who only irritate them by useless arguments or misplaced ridicule: they ought to be separated from society, and placed in an appropriate habitation, to ensure both the safety of the public and their own preservation. Their friends are always repugnant to put this plan into execution: a mother, a wife, or a husband, can with difficulty believe that the object dearest in the world to either of them can be better placed in the hands of strangers than under the influence of those who are eager to devote the most affectionate cares; they fear likewise that in lunatic asylums the sight of the patients will have a bad effect upon their friend, and aggravate the disease; that constraint, severity, and all kinds of bad treatment will be employed to manage the patients, and, if once cured, they will preserve a horrible impression of their abode, and resentment against their relations who have consented to their confinement. These last considerations induce rich families to place their deranged relatives in private houses destined to receive a single lunatic, who is surrounded by servants and inspectors whom he does not know. Besides that these private establishments are very expensive, they rarely answer the end proposed; either some relation chooses to remain near the invalid, or the latter soon perceives that every thing by which he is surrounded is destined for his service; in either case the objects of seclusion are imperfectly attained. Lastly, many things are often required which are only to be found in public establishments. This imperfect separation, however, is all that can be adopted in some families, and we must make as much advantage of it as we can. In public asylums the seclusion is complete; the patients soon know that they are under the authority and even at the discretion of the director; they are watched and constrained without difficulty, under the care of regular attendants. They find powerful sources of occupation and of distraction in associating even with the other patients. The greater number of lunatics never discover that they are in the midst of mad people, and find nothing to complain of in this circumstance. When their reason begins to return, they are removed into the apartment destined for the reception of convalescents, and hence are withdrawn from sights which might make unpleasant impressions upon them. As long as the disease continues, they are angry with those who have deprived them of their liberty; but as soon as they have recovered their reason, resentment is changed into gratitude. On this account, then, the friends of the insane incur no risk. We do not pretend to deny that this separation and abode among other lunatics has occasionally aggravated the disease, when of recent occurrence, in some individuals: on the other hand, we affirm that the same means have cured many lunatics almost immediately. Besides it is next to impossible to preserve and take care of maniacs or monomaniacs in the midst of their family, and all the inconveniences of separation disappear under the absolute necessity of its use."

The same writer has briefly summed up the principal circumstances to which attention ought to be paid in the construction or choice and in the management of an asylum or house of recovery for lunatics. He has collected these remarks from the writings of Pinel and Esquirol.

"1. M. Pinel has particularly insisted upon the necessity of classing lunatics, of separating such as are liable to injure themselves or others, and permitting those to associate together who may contribute to each other's cure. A lunatic asylum ought, then, to be composed of several parts more or less insulated. There should be a quarter ap-

propriated for each sex, a division for violent lunatics, a second for those that are tranquil, a third for convalescents, a fourth for lunatics who labour under accidental disorders. It will be very useful to have a division for those who are of melancholy habits, and in a state of dementia, and another for furious and noisy patients, and for some lunatics who are of an untameable character, and are confined by way of punishment. It is above all things necessary to separate the sexes, the convalescents, and likewise those patients who have depraved habits and indecent manners. Each division ought to have a court planted with trees, and, if possible, a garden for the patients to walk in.

"2. M. Esquirol, who has devoted his attention to the arrangements which these establishments require for the convenience of the patients, to facilitate vigilant superintendence and attention, and to prevent accidents, is of opinion that such houses should be built on level ground; that the cells destined for violent patients should be spacious, with a door and window opposite each other, and opening from without; that they should be boarded and not paved, furnished with a bed, firmly fixed in the wall; that all the cells should communicate with covered galleries or corridors, in which the patients may walk in bad weather, and by means of which the inspectors and servants may easily traverse the different parts of the establishment; that all the rooms should be warmed by pipes of hot air; that abundance of water should be furnished by fountains to wash the dirty cells; that the privies should be separated in such a manner as to occasion no inconvenience to the patients; that there should be places appointed for a general work-room, for a common dining-room, for baths and shower-baths. In this plan of M. Esquirol's there are dormitories only for convalescents, melancholy patients, idiots, and individuals who are debilitated. For others little cells with one bed are preferable, in almost every case; during the day the patients can go out and associate with others, and in the night they do not require companions.

"3. Beings deprived of reason, who fancy themselves reasonable, who incessantly desire and demand things that cannot be granted them, and who are nevertheless sensible to kind as well as to bad treatment, must needs be difficult to influence, to govern, and to cure. As long as each person continues insane, he looks upon the director and inspectors of the establishment as accomplices in the power which has deprived him of liberty, and upon the attendants as inhuman jailors. Even after his cure he is not always very grateful. The director, the inspector, and the attendants, will invariably be objects of prejudice, suspicion, and hatred to the patients; they will receive abuse and often blows from them. On the other hand, it is impossible for one who has not had for a long time the care of them, and studied their disease, to know the mental disposition of lunatics. Without such preparation we should attribute to wickedness what is the effect of disease, or look upon lunatics as beings deprived of all sensibility. In either case we might be induced to treat them with severity. It is almost impossible to make servants understand that mad persons have the use of some of their faculties, with the exception of those servants who have been themselves attacked by the disease. At the Salpêtrière and the Bicêtre great advantage is derived from employing persons who have been cured to take care of the patients. The physician of a lunatic asylum ought to be particularly careful to instruct the individuals who are to have the management of the patients.

"4. It is absolutely necessary that a judicious arrangement of authority and subordination be established in lunatic asylums, and that the physician be invested with a power superior to all with regard to every thing that concerns the patients."

The chief points on which the moral cure of madness turns are thus summed up by M. Georget.

"We may refer to three principal heads all the regulations that can be put in practice with reference to the discipline and exercise of the mental powers in lunatics. 1. Never to excite the ideas and passions of the patients upon the subject of their delirium. 2. Never directly to oppose their unreasonable ideas and opinions, either by argument, discussion, opposition, contradiction, or ridicule. 3. To fix their attention upon subjects foreign to their hallucination, and communicate to their minds new ideas and affections by means of different impressions.

"According to the first principle, we should withdraw the patient from the causes which have excited his madness, and even from objects which might recall these causes, or suggest any allusion to them. Lunatics attacked with religious melancholy should be deprived of their books of devotion; they should not be permitted to engage in offices of religion. Those who are tormented with sexual desires render these desires more imperious by gratifying them, if they do not destroy their health. We ought never to flatter the chimeras of kings, of princes, of gods, of queens. We should never put the patients attacked with the same kind of insanity together, because they would talk incessantly of their conceits, and thus cause to each other a great deal of injury. Thus, as in other diseases, we ought to leave the over-excited part at rest.

"According to the second rule, we should never attempt to reason with lunatics in order to bring them to their senses, for their errors are necessarily connected with their disease. The most evident proofs are of no weight upon the mind of a lunatic. He will suspect that there are secret reasons for deceiving him. Discussion, opposition, contradiction, irritates the disease, and inspires defiance and hatred. In accordance with the third rule, we should make it a point to occupy the mind, and to direct it by different means, such as exercise, work, play, the society of other patients, sane persons presiding over them; by music, reading, conversation, the visits of friends, &c. We should oppose one passion to the ruling passion, and on some occasions excite the activity of feeling by strong emotions, by means of fear, or the sudden announcement of bad news. But these different means are applicable neither in every case nor at every period of the disease. It is in general very difficult to turn for any length

of time the attention of the patients from the subject of their delirium; it is above all things difficult to engage them in occupations either of work or amusement. Very often the disorder of their minds is such that they are continually under the influence of their delirium; they exist in their illusions, and their attention is hardly arrested by the objects that surround them. Restoration to their friends should never take place until the convalescence of patients is perfectly established, and even then great precautions must be used to manage the first interview, to prepare the mind of the patient and of the relatives, and to fix the subject and length of their conversation.

"An active and constant inspection exercised over the patients and the attendants is very necessary in a lunatic asylum. Patients who evince a disposition to suicide should never be lost sight of for a single instant, whatever they may say or do to obtain their wish. It is often necessary to confine violent patients with the strait-waistcoat. Those who are addicted to indecent practices,—a circumstance by no means infrequent,—should be restrained by similar means. Occasionally it is better to confine them by shackles on the legs, fastened down in an arm-chair, or shut up in their rooms, according to circumstances. The use of chains is almost entirely abandoned, and we are indebted to the noble efforts of our venerable Pinel for this improvement in the lot of lunatics." (It may be observed that M. Foville ascribes to the Quakers who have managed the "Retreat" the credit of having been the first to discard these inhuman instruments of restraint.) "At the time of the abolition of chains at Bicêtre, M. Pinel observed that the diminution of the number of furious lunatics, and the accidents which they occasioned, was very remarkable. The only measures of punishment that ought to be put into practice are the strait-waistcoat, seclusion in a cell, removal from one division to another, the shower-bath, and some occasional privations. A violent or wicked lunatic, who all at once puts on a menacing appearance, or even commits reprehensible actions, should be immediately surrounded by a number of attendants, approached and seized at the same time on all sides, particularly by those who are behind him. Sometimes great advantage has been found by suddenly enveloping the patient's head in a napkin, which completely bewilders him. In other cases, while persons placed before the patient endeavour to occupy his attention, others advancing from behind easily lay hold of and secure him.

[Of late, it has been proposed, and practised, to abolish totally all personal restraint in the management of the insane; and the course is said to have been entirely effective. The plan is to substitute a rigid system of constant superintendence, of well-preserved classification, and of humane and effective practical management. It has been affirmed, indeed, that in a properly constructed building, with a sufficient number of suitable attendants, "restraint is never necessary, never justifiable, and always injurious in all cases of lunacy whatever." Cases, in which the patients render their clothes and persons filthy, present considerable difficulty, but a warm bath is always ready, into which the patient is put, and well washed, and the clothes are changed as often as becomes necessary. In violent cases, the patient is at times placed alone in a room, well aired and lighted, where there is nothing destructible, and is treated with all the kindness that can be bestowed upon him. If we admit, however, the practicability and efficiency of the system of non-restraint in a large mass of cases, it may be questionable, whether it be of universal application; and were it so, it can rarely happen that establishments for the insane are so well provided with competent attendants, that corporeal restraint can be wholly dispensed with. The experience, however, of the large insane establishments of this country, has sufficiently shown that it can be but seldom necessary.

By a proper classification of the insane, it will be found that there are comparatively few who are incapable of participating in labour or amusement. Every well-devised insane asylum ought, therefore, to be able to employ such of the patients as are fitted for the task in agricultural or horticultural labours; workshops should be provided, and employment of some kind or other be carefully adapted to each individual. The attention, which such occupations require, produces a moral revulsion, and prevents the topic of hallucination from recurring, or, should it recur, from wholly engrossing the mind of the lunatic. This is now so well understood, that in the different insane establishments it is an object of solicitude on the part of the medical superintendent; and the results have been most salutary. The reports of these institutions sufficiently testify to the interesting fact, that however perverted may be the reasoning powers, there are but few who are unsusceptible of appropriate appeals, when judiciously made. Fifty years ago, it would not have been credited, that numbers have attended public worship in the chapels of those institutions, and conducted themselves with the greatest decorum, who in the halls were noisy, talkative, and profane.]

Sect. VII. — Puerperal Madness.

This term is chiefly and most correctly applied to a form of insanity incident to puerperal women. By some writers, the same expression has been so extended in its meaning as to comprise that species of derangement peculiar to females who are debilitated by suckling, and which commences in general several months after child-birth.

Symptoms of insanity occasionally display themselves during pregnancy, and under circumstances which indicate that they are dependent on that state. These cases are rare in comparison with those which occur after delivery. M. Esquirol mentions the instance of a young woman, of very sensitive habit, who had attacks of madness on two occasions, each of which lasted fifteen days, having commenced immediately after conception. The same writer observes also that several women at the Salpêtrière have become maniacal during the time of their pregnancy.

Cases of puerperal madness, properly so termed, that is, coming on after child-birth, are by no means infrequent. M. Esquirol has related that among 600 maniacal women at the Salpêtrière,

there were 52 cases of this description. In another report by the same writer, there were 92 similar cases among 1119 insane females admitted during four years into the above-mentioned hospital. M. Esquirol is of opinion that the proportion is still greater in the higher classes of society, since out of 144 instances of mental disorder, occurring in females of opulent families, the symptoms had displayed themselves, in 21, either soon after child-birth or during the period of lactation. Dr. Haslam enumerates 84 cases of puerperal mania in 1644 cases admitted at Bethlem. Dr. Rush, however, reckons only five such cases in seventy, received into the hospital for lunatics in Philadelphia.

There is no peculiarity in the phenomena of puerperal madness by which this disease is distinguished from other examples of insanity. Dr. Gooch has remarked that "if a physician was taken into the chamber of a patient whose mind had become deranged from lying-in or nursing, he could not tell by the mere condition of the mind that the disease had originated in these causes."

Those cases which are more properly termed puerperal, as occurring in the first period after child-birth, are generally of the character of mania, attended with excitement of the feelings and mental illusions; while the disorder which displays itself in women exhausted by suckling, is most commonly connected with melancholy depression, a tendency to which may generally be perceived in females who nurse their children too long, with reference to the strength of their own constitutions. Cases of the former description occur within a short period, and most frequently within a fortnight after delivery. They appear sometimes to be occasioned by fright or other accidental causes of disturbance; sometimes by errors in diet, or by premature exertions or excitements: in other instances they take place independently of any discoverable external cause. The patient passes one or two restless nights, appears unusually excited and irritable, talks loudly and incessantly, and very soon betrays a disturbed intellect. The attack is often attended with febrile symptoms. This is the case especially, as Dr. Burrows has observed, if it takes place about the fourth or fifth day, when the secretion of milk is producing a new excitement. The state of the pulse is the most important symptom in reference to the nature and treatment of the case, as well as to the prognostic which is to be formed of its result. Dr. Gooch has laid particular stress on this circumstance, and he has extracted a valuable passage which bears upon it from the manuscript lectures of Dr. Hunter. "Mania," said this eminent practitioner, "is not an uncommon appearance in the course of the month, but of that species from which they generally recover. *When out of their senses, attended with fever, like paraphrenitis, they will in all probability die;* but when without fever, it is not fatal, though it (i. e. fever) generally takes place before they get well. I have had several private patients, and have been called in when a great number of stimulating medicines and blisters have been administered, but they have gone on as at another time, talking nonsense, till the disease has gone off, and they have become sensible. It is a species of madness they generally recover from, but I know of nothing of any singular service in it."

Dr. Gooch's comment upon this passage is the remark, supported by his own observation, that there are two forms of puerperal mania: one of them is attended by fever, or rather by a rapid pulse; the other is accompanied by a very moderate disturbance of the circulation. Cases of the latter kind, which happily are by far the most numerous, terminate in recovery; the former are generally fatal.

Terminations of Puerperal Madness. — Puerperal madness terminates, in a great proportion of cases, either in death or in the recovery of reason. Few instances, comparatively, become cases of permanent insanity. It is, however, very difficult to obtain accurate information on this subject. Dr. Gooch has observed that the records of hospitals contain chiefly accounts of cases which have been admitted because they had been unusually permanent, having already disappointed the hope, which is generally entertained and acted upon, of relief by private care: the cases of short duration, which last only a few days or weeks, and which form a large proportion, are totally overlooked or omitted in the inspection of hospital reports. This remark accounts for the unfavourable nature of the results which are obtained from such tables as those given by M. Esquirol and others. By this writer, ninety-two cases are enumerated, of which fifty-five recovered, and six died, leaving thirty-one as the number of incurables, that is, one in three. Of the fifty-five recoveries, thirty-eight took place within the first six months. Dr. Haslam says that of eighty-five cases admitted at Bethlem, only fifty recovered, leaving thirty-five as the number of incurables. Dr. Burrows mentions fifty-seven cases, of which thirty-five recovered, and eleven remained uncured; of the recoveries, twenty-eight took place within the first six months. Dr. Gooch has remarked that these tables throw but little light upon the real proportions of recoveries, and present a prospect unnecessarily gloomy and discouraging. He adds, "Of the many patients about whom I have been consulted, I know only two who are now, after many years, disordered in mind, and of them one had already been so before her marriage."

The question, on the solution of which there is the greatest reason for anxiety in reference to any particular case of puerperal madness, is, whether it is likely to be fatal; because, if not fatal, there is great probability of ultimate recovery. The most satisfactory way of coming to a conclusion on this inquiry, in any individual case, is by the prognostications which the particular symptoms afford, and on this subject we can add little to what has already been said. The principal danger which menaces life, in cases of this description, is a state of extreme debility; the excitement of the vascular as well as of the cerebral functions, is so great as to wear out the strength, already at a low ebb, and neither recruited by nutrition nor by sleep, and the patient sinks from exhaustion. Experience has proved that a rapid circulation is the principal circumstance which tends to bring on this state. A very frequent pulse is the most

unfavourable symptom. Long-continued resistance to sleep, and a state of complete restlessness, and the appearance of great weakness and inanition, give likewise reason for apprehension. If these signs are not found, the mental derangement of the patient need not give occasion to very serious alarm.

Medical authors have sought to found a prognostic in puerperal madness on the estimate of the proportions which deaths bear to recoveries. This cannot afford evidence on which so much reliance may be placed as on the symptoms of individual cases. Out of the ninety-two cases mentioned by M. Esquirol, of which fifty-five terminated in recovery, there were, as we have observed, six deaths, and in Dr. Burrows's table of fifty-seven cases there were ten deaths. The former calculation gives one death in fifteen cases, and the latter one in six. But the patients in the Salpêtrière are probably removed thither after the period in which the disease is most dangerous to life. There must have been some circumstance tending to explain the discrepancy in the above-mentioned results. The proportion of deaths given by M. Esquirol's table may be somewhat too low, but we are inclined to believe that the result afforded by that of Dr. Burrows gives a greater mortality than the average number afforded by general experience.

Pathology of Puerperal Madness.—The pathology of this disease involves several disputed questions, which we must not pass over without stating them, although we by no means expect to furnish a solution that shall be satisfactory to all parties.

The first inquiry is whether puerperal madness depends for its immediate or proximate cause on inflammation of the brain and its membranes.

The arguments urged in proof of this opinion, are, in the first place, the result of anatomical examination in cases of madness in general. We must refer to a former section of this treatise on the necroscopical researches into the state of the brain in the bodies of maniacal patients, for evidence on this subject, and for proofs of the general inference that inflammation, or a state closely allied to inflammation, is really the condition of the brain in cases of insanity. As puerperal madness is identified by its symptoms with other forms of insanity, this analogical argument has evidently some weight until it shall be proved that this particular form of mental derangement furnishes an exception to the general fact.

Secondly, the phenomena displayed by dissections in cases of puerperal madness itself, have been thought by some to afford evidence in favour of the same conclusion. Unfortunately there is some discrepancy in the results of anatomical researches in respect to such cases. We have no extensive record of accurately related dissections, which might illustrate on a large scale the pathology of this disease. M. Esquirol says that he has examined the bodies of several patients who have died under puerperal mania, without being able to detect any morbid traces that pointed out the seat of the disease; and Dr. Gooch has given the details of a case, at the termination of which he says, in general terms, that although the body was examined by a very eminent anatomist, no vestiges of disease were discovered in the brain or elsewhere. In several other cases, however, described by the same eminent writer, it must be observed, that although the complaint had occurred in bodies already exanguious from uterine hemorrhage and other exhausting causes, there were discovered on dissection thickenings of the dura and pia mater, sinuses full of blood, serum effused under the arachnoid membrane, hardness of the brain, and numerous bloody points, on cutting the substance of the hemispheres. Dr. Burrows has likewise referred to several cases in which there were marks of cerebral congestion; and in particular to one of Newman's dissections, in which the arachnoid membrane was quite firm, and nearly as thick as the dura mater. On the whole there is sufficient evidence that in general the brain of puerperal maniacs displays, in a greater or less degree, the phenomena which are accounted to indicate the presence of inflammation.

The reasons which in the minds of some writers have over-weighed all the arguments furnished by these observations, are the following: first, that the disorder in question frequently attacks patients who are previously in a state of great exhaustion, and therefore thought unlikely to be assailed by complaints of an inflammatory nature; and secondly, that puerperal madness, as might be expected from the circumstances under which it takes its rise, and the exhausted and debilitated state of many patients who are attacked by it, cannot be safely treated by powerful antiphlogistic measures, such as copious bleeding. "Are we," says Dr. Gooch, "to shut our eyes to the symptoms during life, to the effect produced by remedies, to the mode in which death comes on,—that is, with symptoms of exhaustion, and to the remarkable emptiness of the veins throughout the body; and because there was a little serum under the tunica arachnoides, and more bloody points than usual in the medullary substance of the brain, conclude that it was a disease of congestion or inflammation, and that perhaps the patient died because she was not blooded sufficiently?" This last part of the inference would, indeed, be much more than the premises would warrant; the question, what is, in a pathological point of view, the condition of the brain, becomes comparatively unimportant and almost a matter of mere curiosity, when the practical indications are already given, and even become the data from which we are to deduce reasons as to the nature of the disease. Yet it must be allowed that the existence of inflammation is not disproved by either of the arguments advanced. The disease supervenes on an exhausted state of the system, but so do many other inflammatory complaints. Pneumonic affections often attack women who have suffered much in childbirth from uterine hemorrhage, but we do not for this reason call into question the inflammatory nature of pneumonia. Neither are we authorised in asserting that the disorder is not inflammatory, by the fact that the patients labouring under it do not bear bleeding ad libitum. How many inflammatory complaints are there in which we cannot venture freely on the use of the lancet! Dr. Gooch's observation is, in a practical point of view, of the highest value. Antiphlogistic and evacuant remedies must not be used without the greatest caution in cases

of puerperal madness; but the existence of inflammation in the brain and its membranes, when evidence of it is displayed in the characteristics of vascular fulness and other usual phenomena, is not disproved by this consideration.

The theory of this disease, in reference to the nature of its constitutional and proximate causes, may be different in cases which occur at different periods; and this is the more likely, because these cases vary in respect to their phenomena.

In those instances of maniacal affection which occur during pregnancy, it is probable that the disordered state of the brain or of the cerebral functions is the result of sympathetic excitement, which the vascular system, perhaps that of the brain in particular, sustains from the peculiar state of the uterine functions. The well-known complaints connected with temporary excitement of the brain in some females at the period of the catamenia, the symptoms thence resulting, such as the returns of hysterical, epileptic, cataleptic paroxysms, or of hysterical and sometimes maniacal excitement of the mind, are pathological facts sufficiently illustrative of the affection alluded to, and show it to be in accordance with other morbid phenomena.

When madness comes on after childbirth, the pathology of the case is, perhaps, different from that of the affection now described. Dr. Gooch said, "the cause of puerperal mania is that peculiar state of the sexual system which occurs after delivery." He afterwards thought this account of the matter not sufficiently explicit. "What I meant was this; the sexual system in women is a set of organs which are in action only during half the natural life of the individual, and even during this half they are in action only at intervals. During these intervals of action they diffuse an unusual excitement throughout the nervous system,—witness the hysteric affections of puberty, the nervous susceptibility which occurs during every menstrual period, the nervous affections of breeding, and the nervous susceptibility of lying-in women. I do not mean that these appearances are to be observed in every instance of puberty, menstruation, pregnancy, and childbirth, but that they occur sufficiently often to show that these states are liable to produce these conditions of the nervous system." He adds, "Dr. Marshall Hall thinks that the susceptibility of the puerperal state is to be explained by mere exhaustion, and does not at all depend on the influence of anything specific in the condition of the several organs at that time; but would an equal or greater degree of exhaustion at any time occasion the disease? This is a question of fact which I should answer in the negative. I have seen patients who have been deranged in childbed, and who had recovered, at a future period much more exhausted by illness, and much more agitated in mind, without the slightest appearance of mental derangement."

It would seem that we are here referred for an explanation of the maniacal affection which occurs soon after childbirth, to excitement produced by the state of the uterine system. A remark, however, which obviously suggests itself on this subject is, that the phenomena of puerperal madness usually display themselves just at the period when uterine excitement is subsiding. If ever the uterine functions, or the activity of the whole system of organs connected with them, is suspended, it is during the time shortly following the puerperal period. We should not, at this conjuncture, expect the brain and the mind to be excited by sympathy with organic actions, which are in fact in a state of temporary cessation. But the expression, excitement of the sexual system, which is allowed to be too indefinite to convey a very precise meaning, may include the process of lactation. Perhaps it is to the irritation produced by the secretion of milk that we are more particularly to direct our attention; for this secretion is a part of the series of functions belonging to the sexual system. But here we only return to the popular notion, according to which the disorder depends on the flow of the milk. Such is the opinion of old women and nurses in general, and it may be the true one. The relations, however, of puerperal madness to the different processes which are set up or cease in the animal economy subsequently to childbirth, will be illustrated, if susceptible of illustration, by an exact observance of the periods at which this affection most frequently displays itself. The information obtained on this subject is not so complete as we might desire, but still it is of some value.

Sauvages and other writers have recognised two different forms of mental derangement incident to lying-in women. One of them has been termed "*paraphrosyne puerperarum*," and is observed to succeed labour, immediately or within a day or two, before the secretion of milk can disturb the system, and independently of any lochial suppression. "These attacks," says Dr. Burrows, who assents to the above distinction of varieties in the disease, "will sometimes go off under the operation of a smart purge and an opiate, and may then be considered as merely accessions of delirium; in other instances they are more permanent, and become fully developed instances of puerperal insanity. Sauvages' second species is termed '*mania lactea*;' and Dr. Burrows is of opinion that maniacal symptoms in reality make their appearance most frequently about the third or fourth day after childbirth, which countenances the notion that they are connected with the lacteal secretion. This writer, however, has very candidly referred to the evidence deducible from the tables published by M. Esquirol, although it is rather opposed to the opinion above stated. From these tables it appears that in the years 1811, 1812, 1813, 1814, eleven hundred and nineteen insane women were admitted into the Salpêtrière, of whom ninety-two laboured under puerperal madness: of these—

16 became delirious from the first to the fourth day.
21 from the fifth to the fifteenth day, which generally includes the termination of the lochia.
17 from the sixteenth to the sixtieth day.
19 from the sixtieth day to the twelfth month of lactation.
19 after forced or voluntary weaning.

The result seems to be, as Dr. Burrows allows, that the disease is more frequently a consequence of delivery than of suckling.

On the whole it appears evident that some cause more general in its influence than any one particular process must be referred to, if

we would explain the frequent occurrence of madness in pregnant, puerperal, and suckling females.

A view of this subject which seems to us more illustrative of it, occurred to Dr. Ferriar, and has been thus stated by him.

"I am inclined to consider the puerperal mania as a case of conversion. During gestation, and after delivery, when the milk begins to flow, the balance of the circulation is so greatly disturbed as to be liable to much disorder from the application of any exciting cause. If, therefore, cold affecting the head, violent noises, want of sleep, or uneasy thoughts, distress a puerperal patient before the determination of blood to the breasts is regularly made, the impetus may be readily converted to the head, and produce either hysteria or insanity according to its force and the nature of the occasional cause."

That new determinations in the vascular system should ensue on the removal of one so long subsisting as that to the uterus during pregnancy, is in accordance with a well-ascertained principle in pathology. The natural and healthy determination under these circumstances is to the lacteal glands, but owing to various causes, either external or of predisposition, morbid determinations occasionally take place. Some women become phthisical at a very early period after childbirth, or rather the symptoms of phthisis develop themselves at that time in a manifest form. Other constitutional complaints are apt to arise at the same period, according to the prevalent tendency of the habit. When the brain is susceptible, it is likely to suffer in its turn, and become the seat of local disorder, the manifestations of which are affections of the mind. If we consider the frequent changes of disturbances occurring in the balance of the circulation from the varying and quickly succeeding processes which are carried on in the system during and soon after the periods of pregnancy and childbirth, we shall be at no loss to discover circumstances under which a susceptible constitution is likely to suffer. The conversions or successive changes in the temporary local determinations of blood which the constitution under such circumstances sustains and requires, appear sufficiently to account for the morbid susceptibility of the brain.

The cases of mental disorder which occur in the later periods of lactation are, as it is evident from M. Esquirol's table, of two kinds. In one the disease supervenes on weaning, and probably has its origin in the subsidence of the lacteal secretion. There are other instances which appear to arise from the continued excitement and exhaustion of the system consequent on suckling. This state of exhaustion takes place at different periods in different constitutions. Some women can continue to give milk without injury for years, but by others, morbid feelings are experienced in the space of a few months or even of as many weeks, and do not subside for some time after weaning. The writer of this article has observed very numerous instances of melancholy dejection with symptoms of insanity more or less strongly marked, which have displayed themselves in the protracted period of nursing, and in females who were evidently suffering from exhaustion. In one instance a lady, who on former occasions had complained of feelings termed nervous, and had been much indisposed when giving milk, was persuaded to continue suckling a child until the thirteenth or fourteenth month. She was then attacked by a maniacal disorder, which, though of a mild character, was very decided in its nature. Nearly a year passed before her mind was perfectly restored.

Treatment of Puerperal Madness.—If we consider that the greatest danger to be apprehended for patients labouring under puerperal madness arises from a state of extreme exhaustion, that many women die from this cause within a short interval from the commencement of the disease, and that if they survive this period, the healthy state of the mind is in most instances restored, it will be evident that our chief endeavours must be directed to the present support of life. If we can maintain and restore the general health, and keep the natural functions in a state compatible with continued existence for a time, the disease of the animal system will in all probability subside. Antiphlogistic and particularly evacuant remedies must be used very sparingly and with great caution.

1. Bloodletting, as a general remedy for puerperal madness, is condemned by all practical writers on whose judgment much reliance ought to be placed. M. Esquirol is decidedly opposed to it. Dr. Gooch's observations on this subject contain the best exposition of the rules which ought to guide medical practitioners as to the use of the lancet in cases of puerperal madness. He says, "The result of my experience is, that in puerperal mania and melancholia, and also in those cases which more resemble delirium tremens, bloodletting is not only seldom or never necessary, but generally almost always pernicious. I do not say that cases never occur which require this remedy; no man's experience extends to all the possibilities of disease, but I have never met with such cases, and I would lay down this rule for the employment of bloodletting—never to use it as a remedy for disorder in the mind, unless that disorder is accompanied by symptoms of congestion or inflammation of the brain, such as would lead to its employment though the mind was not disordered. Even here, however, great caution is necessary; local is safer than general bleeding. In one case the head was hot, and the face red, and the pulse was said to have become somewhat hard, yet a bleeding of eight ounces was followed by extinction of the pulse within three hours, and death in less than six. The only cases attended by a quick pulse which I have seen recover were those in which no blood was taken. In the really inflammatory disease of the brain, bloodletting of course is essentially necessary; but these, I think, can never be mistaken for puerperal insanity; they are febrile headachs, more or less acute. Pain of the head with fever is a much better indication for bloodletting than disorder of the mind without these symptoms."

2. In cases attended with much heat about the scalp, flushing of the face, and strong pulsation of the temporal and carotid arteries, it will be proper to shave the head and keep it cool by means of cold lotions, or an oil-skin cap filled with ice or iced water, or by evaporating lotions.

If the symptoms above mentioned and those of mental excitement are very acute, and the debility of the patient is not in an alarming degree, a few leeches may be applied with advantage. Blisters to the occiput or nape of the neck are often serviceable; they are much recommended by practical writers. When the scalp is not hot, and the tendency of the disease is rather to stupor than to a high degree of excitement, blisters are usefully applied over the top of the head.

The lower extremities, which are often cold, should be frequently immersed in hot water, or a hip-bath used. Dr. Burrows recommends bathing the legs and feet in a warm infusion of mustard or horse-radish. Heat should be applied in the most convenient form, and the circulation in the extremities promoted by other obvious means.

3. Purgatives and emetics are among the most useful remedies in this disease. The alimentary canal is frequently in a disordered state, the tongue furred, the breath fetid, the skin discoloured, the evacuations dark and offensive. A few brisk purgative doses, calomel followed by castor oil or rhubarb and magnesia, should be given in such cases. Emetics of ipecacuanha, with small doses of tartarized antimony, are very valuable remedies in this state of the alimentary canal. Dr. Gooch has remarked that they should be used with caution when the face is pale, the skin cold, and the pulse quick and weak; and in general he prefers ipecacuanha to antimonials.

4. After these evacuant remedies have been premised, great advantage is frequently derived from the use of opiates. Full doses are generally attended with the best success. Ten grains of Dover's powders may be given at night, or a grain and a half of solid opium, or thirty drops of the tincture. Several writers recommend Battley's solution of opium in preference to the tincture; perhaps the acetate and muriate of morphia are the best preparations of opium; they may be given in doses of a quarter or half of a grain, and repeated every third or fourth hour until sleep is procured. When opiate disagrees, Dr. Gooch recommends the use of hyoscyamus, mixed with camphor. He says that five grains of each should be given every sixth hour, and a double dose at night: a dram of the tincture will answer the same purpose. This writer is of opinion that narcotics are the most valuable remedy in the cure of puerperal mania; he says "that they often produce nights of better sleep and days of greater tranquillity, and this calmness is followed by some clearing up of the disorder of the mind." He says that these remedies produce salutary effects much more frequently in the mania of lying-in women than in maniacal disorders occurring under other circumstances; if, however, there is heat in the head, flushing in the face, and thirst, their use ought to be postponed until such symptoms shall have been removed.

5. In the more protracted cases of puerperal madness, tonic and stimulant medicines are sometimes requisite, especially when the appetite has failed. Ammonia is much recommended. It may be given with infusion of cinchona or any bitter infusion. When it is not offensive to the stomach, the rectified oil of turpentine is one of the best stimulants, especially if taken in the dose of a drachm three times in a day with cinnamon water, or any other aromatic fluid.

6. A rule of great importance refers to the *diet* of women in puerperal madness. It may, perhaps, be safely asserted that the greatest risk which patients in this disease incur is that of being starved through the mistaken notions of their attendants, who are too often disposed to consider the excitement of maniacal disease a reason for withholding food, when this very state, owing to the exhaustion produced by its long continuance, renders it especially necessary to support the strength more carefully. Farinaceous fluids of a nutritive quality, milk, rice, and other such matters should be given at short intervals, when febrile symptoms preclude the use of animal food. In most instances broth may be allowed and ought to be given. In the more protracted periods, solid meat, with malt liquors, should be taken. We have seen very many maniacal patients labouring under great weakness and exhaustion, with cold extremities, a clammy skin, passing sleepless nights, and under continual agitation, begin to improve as soon as their diet was changed, and meat with some ale or porter given daily. The pulse has become fuller and less frequent, the extremities warm, sleep has been restored, and convalescence has taken place in a surprisingly short period after such a system has been adopted.

7. The last observation to be made refers to the *management* of such patients. We must here advert to the remarks to be found in a former section on the management and moral treatment of maniacal patients in general. The general rules only require modification in some particulars in relation to the peculiar circumstances of puerperal patients. The latter for obvious reasons cannot be soon removed from home. They require in other respects similar management. They should be separated from relatives and friends, and carefully attended by persons who are fitted for the occupation by habit. It will not so often be necessary to send puerperal maniacs to lunatic asylums as deranged persons of a different description.

Sect. VIII.—Senile Dementia.

Senile dementia is essentially distinct from insanity; yet for various reasons that will be apparent, a short account of its phenomena will be properly introduced in this place.

We have already described that species of fatuity which is the frequent result of protracted insanity. The term dementia has been adopted by late writers to designate this morbid state of the mental faculties. This expression, however, has been used in a somewhat more extensive sense, as equivalent to fatuity in general, and as denoting, besides the ordinary sequel of madness, various other morbid conditions, in which the intellectual powers are impaired or obliterated. It is applied to the fatuity which occasionally follows apoplexy, epilepsy, palsy, and other comatose diseases. By many French authors the same term has also been made to comprehend the mental disease or decay peculiar to old age. In its last stage fatuity displays nearly the same phenomena in every case, by whatever causes induced or by whatever previous diseases it may have been ushered in; but in the early periods, to which,

for reasons already explained, we purpose to limit the application of the term dementia, there are many shades of difference between its different forms. The intellectual weakness which follows apoplexy is not precisely of the same character as that demented state which is the sequel of insanity, and which occasionally gives way either to a renewal of maniacal excitement or to returning reason; nor is either of these affections precisely analogous to the decay of mind incident to old age. We must, in compliance with custom, continue to use the received term, but we shall distinguish the last-mentioned affection by the additional epithet of *senile* dementia.

The following is the description of dementia in general which has been given by M. Esquirol. "Dementia deprives men of the faculty of adequately perceiving objects, of seeing their relations, of comparing them, of preserving a complete recollection of them; whence results the impossibility of reasoning correctly. Demented persons are incapable of reasoning, because external objects make too feeble an impression upon them; because the organs of transmission have lost a part of their energy; or, lastly, because the brain itself has no longer sufficient strength to receive and retain the impression which is transmitted to it; hence it necessarily results that the sensations are feeble, obscure, incomplete: being unable to form a true and just idea of objects, these persons cannot compare them, or exercise abstraction or association of ideas; they are not capable of a sufficiently strong attention; the organ of thought has not energy enough: it has been deprived of that vigour which is necessary for the integrity of its functions. Hence the most incongruous ideas succeed each other; independent of each other, they follow without order and connection; patients repeat words and entire sentences without attaching to them any precise meaning; they talk, without being conscious of what they say. It seems as if unreal expressions were heard by them in their heads, which they repeat in obedience to some involuntary or automatic impulse, the result of previous habits or of fortuitous association with objects which strike their senses."

Senile dementia differs in many particulars from the state of disease just described, though in some others resembling it. There is in both cases the same speedy and almost momentary obliteration of recent impressions, if the merely passive recognition of objects which present themselves to the senses may be so called. But in the disease peculiar to old age it may often be observed that ideas which were long ago stamped upon the mind remain with nearly their original force, and are capable of being called up whenever association suggests them, or the attention is purposely directed to them. The impressions produced by present objects are often so slight and evanescent, and the notions connected with them are so confused and indistinct, that the individual affected scarcely knows where he is; yet he recognises without difficulty persons with whom he has long been acquainted, and if questioned respecting his former life and the transactions and pursuits of his youth or manhood, he will often give pertinent and sensible replies. The disorder of his mind consists not in defective memory of the past, but in the incapacity for attention and for receiving the influence of present external agencies, which, in a different state of the cerebral organization, would have produced an effect upon the sensorium, or seat of sensation and perception.

The following account briefly describes the state of a person labouring under senile dementia, who has been occasionally under the care of the writer of this article. It will serve to exemplify some of the foregoing remarks.

A. M———, aged about seventy years, was in his youth a farmer, but changed that occupation for the business of a baker, which he followed until he had accumulated property sufficient for his maintenance. He has been living for several years in retirement, and without any regular occupation. His memory is said to have undergone a gradual decay. When he is questioned respecting present objects and circumstances, he generally gives clear and distinct answers, but can seldom recollect what has occurred but a short time previously. In half an hour after he has been visited by his medical attendant, who is an intimate acquaintance, he will say, if asked, that he has not seen him for several days. His recollection of persons whom he knew in the former periods of his life, and of events which then happened to him, is tolerably clear; but at times, and especially after sleep, he does not know where he now is. He sometimes fancies, at night, on waking from a short sleep, that he is engaged in his former occupations. He has risen from bed, and set himself busily to prepare for lighting a fire in his oven, beats the wall, calls his men up, and asks if the fagots are ready. He cannot be persuaded without great difficulty that he is in ——— street, and has nothing to do with the baking business. At other times he will get up in great haste to go down and see somebody who is waiting for him on business, or thinks that there is a horse standing for him at the door, calls for his clothes, and wonders that his friends are so tardy in assisting him. At these periods his state is not that of ordinary somnambulism. He sees and knows some at least of the persons who are about him, and will converse with them. He sometimes, during the day-time, wonders where he is, does not know the place though he has resided in the same house for some years. The hostess, who is an old acquaintance, at length convinces him that he is at her home. When his recollection is roused, and his thoughts are drawn into the right channel, he has a correct knowledge of persons, and shows not the slightest trace of maniacal illusions, or of anything approaching to the character of insanity. He is glad to see his old friends, shakes hands with them in his wonted cordial manner, is on the best terms with his relatives, and never displays the least deviation from the natural and habitual state of his feelings and affections.

Senile dementia, or the decay of the mental faculties, is not the lot of old persons universally, though it is a condition to which old age may be said to have a tendency, and to which in the last stage of bodily decay some approximations are generally to be perceived. The change which time alone will perhaps sooner or later bring on, in those who long survive the allotted duration of man's days, may be accelerated by a variety of

circumstances. Among these is a life of too much activity and excitement, of mental exertion beyond what the constitutional strength of the individual is capable of supporting without constant effort; excessive anxiety and eagerness in the pursuit of business, or intense and unremitted application to studies of whatever kind. The minds and bodies of men are only fitted for exertion in certain degrees, which, however, differ in different individuals; but the powers of all are limited. All have need of occasional respite from labour, and the appointment of rest during one day in seven is, from physical considerations alone, calculated to promote the well-being of individuals and of society. We may observe that among those who neglect this ordinance, there have been many who have suffered the penalty in this life. Some have terminated a rapid and perhaps brilliant career of unremitting and successful exertions by suicidal madness, of which too many and too well-known examples might be cited; others, though in a longer measure of time, have accelerated the period of intellectual decay.

A second cause of senile dementia, next in the frequency of its operation to that which we have just mentioned, is the too liberal use of vinous or other fermented liquors. There are many persons who lead active lives, who are not considered intemperate, yet drink on an average nearly a bottle of wine a day. Such persons, if their lives are not shortened, have every reason to expect a premature imbecility. The same affection has been observed frequently to make its appearance in men long engaged in active pursuits, soon after they have relinquished their business or professions, and have laid themselves by to enjoy ease and leisure for the remainder of their days. The disease often appears in a more marked and sudden manner in elderly persons who have sustained a slight attack of apoplexy or paralysis, which has perhaps been speedily recovered, and expected to have left but slight traces of disease. That expectation is verified so far as the sensitive and motive powers are concerned, but the seat of intellect is found to have been shaken in its very centre.

Senile dementia is entirely distinct from that species of moral insanity which appears occasionally, as we have already observed, in aged persons. The former is merely a loss of energy in some of the intellectual operations. It brings with it nothing morbid or unusual in the state of the feelings or affections, no tendency to depraved or unaccustomed habits, nor, commonly, any change in the temper and general disposition of mind. Individuals to whose lot this complaint has fallen are seldom unhappy on account of it, and if they are in any degree aware of their condition, they bear it with patience and cheerfulness. The state of the affections remaining natural and unperverted, is indeed a general diagnostic between disorders consisting merely of impaired faculties, and the forms of madness. The reverse of the previous remark applies, as we have said in the former part of this treatise, to the various modifications of insanity, and probably in greater or less degree to every case which can with perfect propriety be designated by that term.

This last observation, in its reference to senile dementia, may suggest a hint as to the justice and propriety of certain proceedings which are occasionally attempted and put in force with persons labouring under that affliction. As madness not only disorders the intellect, but likewise perverts the moral habits and the natural feelings of the afflicted individuals who are victims to it, there arises hence an obvious and unquestionable propriety in putting them under restraint. They are then not only placed under circumstances more favourable and sometimes essential to the cure of their complaint, but are likewise prevented from committing acts dangerous to themselves and others, and such as the same individuals would perhaps have shuddered to reflect upon in the days of sane and unclouded reason. To act otherwise with them would indeed be the height of cruelty. But the case is widely different when the moral disposition and the entire mental character remain unimpaired, and the memory only fails, or the aptitude to intellectual exertion alone is diminished through the weakness of years. If an old man, who has spent the greatest portion of his life in active exertion, and has accumulated property by habits of labour and parsimony, after some time passed in retirement, begins to lose his recollection of passing events; if his faculties become impaired to a certain degree on account of that wealth which it has been the object of his life to accumulate, and for the amassing of which he has sacrificed all thoughts of ease and comfort during many successive years, he may now become the object of attack to some relative who may procure declarations of his incompetency to manage his estate. If such a person is brought before a jury and sharply interrogated, examined in figures, and puzzled by a variety of questions respecting matters of business, and other topics requiring accuracy in dates and calculations, it is not impossible that the affair may issue in his confinement in a lunatic asylum, or that at all events the management of his person and his affairs may be taken from the care of those to whom in the sound and entire state of his faculties he had confided both, and to whom, his moral affections and social feelings remaining yet unchanged, he still continues to be devotedly attached.

In France it has been for many years not unusual to confine aged persons of impaired faculties in the public *hospices* where deranged persons are admitted; and this practice has so much prevailed, that M. Georget alludes to it as a source of error and embarrassment in the attempt to determine the relative frequency of madness in late and in former times; these asylums being partly occupied by a number of old persons who remain till their decease, and whose disorders are not properly cases of insanity. Previously to the year 1790, out of 411 persons admitted as labouring under disordered or decayed intellect, there were only 19 whose age exceeded fifty years, whereas, in 2451 admitted between 1814 and 1821, not less than 880, or the third part of the entire number, were persons who had passed the period of life above mentioned. Of these, a great proportion were probably cases of senile decay. If the custom of thus getting rid of aged parents were a matter of choice and in general practice, without excuse on the ground of necessity, we might doubt whether

our enlightened neighbours displayed their filial piety in a more advantageous manner than the Battas, who knock their aged relatives on the head and eat them; or than the old Irish, who, as Strabo assures us, καλὸν τι ἡγοῦντο κατεσθίειν τοὺς πάτερας τελευτῆσαντας. But it is only among poor families that the custom prevails, and it is but parallel to the habit of the poor in England, who not unfrequently suffer their parents to die in parish workhouses. It is the greatest evil attendant on iron-handed necessity, that it so often breaks asunder the first and nearest bonds of duty and natural affection.

The following table will serve to illustrate the forms of disease which are included by medical writers under the common term of dementia. It is styled by M. Esquirol, from whom we extract it, a table of causes. The table exhibits the distribution of 235 cases of dementia; the first column contains the number of patients admitted at the Salpêtrière during the years 1811 and 1812; the second column is the report of the author's private establishment, and is limited to persons of the higher or more opulent classes of society.

TABLE OF CAUSES.

	No. of Individuals.		Total.
Physical Causes.			
Disorders connected with the catamenia	11	4	
Critical period	29	6	
Consequences of childbirth	5	3	
Blows upon the head	3	0	
Progress of age	46	3	
Ataxic fever	1	2	
Suppression of hemorrhoids	0	2	
Mania	14	4	195
Melancholia	13	2	
Paralysis	3	2	
Apoplexy	3	2	
Syphilis and abuse of mercury	6	8	
Faults of regimen	0	6	
Intemperance	9	6	
Masturbation	4	7	
Moral Causes.			
Disappointed love	1	4	
Fright	4	3	
Political excitement	0	8	
Disappointed ambition	0	3	40
Poverty	5	0	
Domestic griefs	8	4	
	192	73	235

It may be remarked in reference to the first column, that the cases placed under the heads, 1, 2, 3, 8, 9, 12, 13, 14, 16, 18, 19, 20, 21, amounting altogether to 102, were probably instances of insanity in some of its forms, or of the stages of fatuity which are its consequence. There only remain 60 cases, which appear to have been instances of dementia not preceded by madness. Of this remainder, 46 cases are examples of senile decay, and these appear to form the great majority of cases, which are referred by the writer above cited to the head of idiopathic dementia, or dementia, unconnected with insanity. It therefore appears that this class of diseases nearly resolves itself into the sequelæ of madness, and the decay peculiar to old age.

It is obvious that the art of medicine in reference to senile dementia must be limited as to its sphere, in a great measure to the means of prevention, as cure is scarcely to be hoped. The prevention of this melancholy termination must, however, depend upon the habits of the individual, and on the mode in which the previous years of life may have been passed. In the regulation of previous habits may be found resources adequate in general to averting the approach of mental decay. Much will depend upon the manner of living during the early period of old age, or when the physical powers are beginning to decline. Habits of indolence, and those of too great mental exertion, should be alike avoided; since many are observed to lose the vigour of their minds after a sudden and total retirement from active business, while in others the disordered state seems to have been brought on by too close application to studies, and particularly to those which require a sedentary life. The former of the causes above mentioned is, however, by far the most powerful and frequent in its operation, and numberless instances may be cited of persons who have exercised professions requiring considerable labour of mind during advanced years, without experiencing in consequence any decay of faculties.

The preservation of health in old age, both in other respects and in what regards the functions of the brain, will depend, in a very considerable degree, upon the adaptation of diet and regimen to the constitutional state of elderly persons. With the alteration of habits which advancing age implies, with the various changes in the state of the physical functions which it brings with it, a corresponding variation in diet and regimen is necessary, and if this is not made, disorder ensues. Many of the diseases incident to elderly persons are diseases of plethora, as apoplexies, and paralysis, and vertigo, and these are not unfrequently the preludes of dementia. The decay of faculties is observed to occur without such preludes in persons who live too freely. These and other considerations render it probable that the disorder of the brain connected with senile dementia depends upon a state of vascular repletion. When the disorders of old age have commenced, by a comparatively spare diet, consisting principally or entirely of farinaceous and other light vegetable food, by discontinuing in a great measure the use of wine and fermented liquors, the general health, and that of the brain in particular, will be greatly promoted. If there are decided threatenings of cerebral disease, an issue or seton, and the frequent use of mild aperient medicines to maintain a copious alvine discharge, will contribute to the same end, and will not only ward off attacks of apoplexy and palsy, but likewise lessen the tendency to senile dementia.

[The preparation of the above article suggested to Dr. Prichard his *Treatise on Insanity and other Diseases affecting the Mind*, (Lond. 1835,) which was reprinted in this country. It is a comprehensive and able work, and may be referred to for further developments of the subject. See, also, Art. Insanity, in Copland's *Dictionary of*

Practical Medicine; Esquirol, *Des Maladies Mentales*, Paris, 1838; and, for the arrangement, &c. of insane hospitals, Jacobi, Art. Irrenanstalten, in *Encyclop. Wörterb. der Medicin. Wissenschaft.* xix. 62: Berlin, 1839; and *On the Construction and Management of Hospitals for the Insane, with Introductory Observations*, by Samuel Tuke, Lond. 1841. A good account of the American insane institutions is given in the First Report of the Insane Asylum at Utica, N. Y.; also, in the Eleventh Annual Report of the Trustees of the State Lunatic Hospital at Worcester, Mass. Boston, 1844.

J. C. PRICHARD.

INTERMITTENT FEVER.—See FEVER.

[INTUSSUSCEPTION, (from *intus*, within, and *suscipio—sus* or *sub* and *capio*, to take.) Intussusception or invagination of the intestines occurs when one portion of intestine passes into another. Owing to augmented peristaltic or spasmodic action of the intestines, an upper portion of intestine may be forced into a lower; or, should an inverted action of the intestines occur, it may happen, that the lower portion is forced into the upper, and becomes arrested there. The first of these lesions is called *progressive* intussusception; the latter *retrograde* intussusception.

Invaginations are not unfrequently met with in the dead body, especially in children; but these often occur, probably, as one of the last acts of life; whereas, the invagination, that gives rise to the concatenation of phenomena termed *ileus*, is accompanied by an inflammatory process, which causes the adhesion of the peritoneal surface of the invaginated portion of intestine to the portion of the peritoneal surface of intestine with which it comes in contact, so that the intussusception cannot be reduced after death. Owing to the narrowness of the canal, and the resulting obstruction, the phenomena induced by obstruction from whatever cause, or, in other words, those of ileus supervene.

Intussusception may take place in any part of the alimentary canal; but it is most frequently observed in the ileum near where it terminates in the colon. At times, the invaginated portion sloughs away; and there have been cases in which as much as three feet of intestine have been discharged *per anum*, with more or less of the mesentery attached. In thirty-five cases, collected by Dr. Thompson, (*Edinburgh Medical and Surgical Journal*, October, 1835,) the average duration of the disease was between four and five weeks. In twenty-two, the evacuated portion belonged to the small intestine; in the other, to the large, or to both. Where the invagination has proceeded to a great extent, or where the small intestines with the cæcum have passed down into the sigmoid flexure of the colon, as in some cases that have been related, the seat of the disease is manifested by a hard tumour; and in less marked cases careful examination has detected the existence of a deep-seated tumour.

Treatment.—From the obscurity that must necessarily exist as to whether the phenomena of ileus be produced by intussusception or some other cause of intestinal obstruction, it is difficult to direct an appropriate treatment. Should it be diagnosticated, or suspected, cathartics must of course be very questionable remedies; and the only hope we can have is, that the invaginated portion may be thrown off, and a cure be thus obtained; although such a result, it must be admitted, is extremely rare. The appropriate general treatment, in all such cases, is that advised under enteritis (q. v.);—bloodletting, general or local, or both, with full doses of opiates, the warm bath, &c.

Metallic mercury has been recommended by most writers in intussusception, as well as in every case of obstruction of the bowels; but it is not easy to comprehend on what principle it has been advised in intussusception. If it be of the progressive kind, the mercury must proceed directly through it; and if retrograde, the same thing might happen, or, if not, by passing between the intestinal and the invaginated portion, it might aggravate the disease.

It has been supposed that large quantities of water or air thrown into the bowels might cause the invaginated portion, in cases of progressive intussusception, to resume its proper position; and it has been proposed in suspected cases to introduce long bougies, and even pieces of whalebone, into the rectum, with the view of pushing back the intussuscepted portion; but cases can hardly be imagined in which such agents can be appropriate. Emetics have been suggested in cases of progressive intussusception, yet they could only be of service before agglutination of the peritoneal surfaces has occurred; and, besides, one of the evidences of intussusception is the antiperistaltic action and vomiting. Under the same reasoning, cathartics might be advised in the retrograde form!

Where evidence has happened to be very strong as to the existence of intussusception and its seat, the operation of laparotomy has been advised, with the view of disentangling the invaginated intestine; but it has been wisely discountenanced by almost all therapeutists. The symptoms of intussusception are always, indeed, obscure and doubtful, and may be produced by other states of the digestive tube; so that, if the abdomen were opened, it might be found that no intussusception existed; or if it did, that, owing to the agglutination, no separation could be effected without causing, if possible, a more speedily fatal lesion. These circumstances, consequently, render the operation wholly inadmissible.

ROBLEY DUNGLISON.]

IRRITATION.—It is remarkable that a term so commonly employed and so indispensable as this is, should never have received a definite and generally acknowledged application. The agents and subjects, the causes and effects, the influences and phenomena of disease, have all indiscriminately passed under the name *irritation*, until the word has ceased to designate anything, and, "vox et præterea nihil," is prostituted to pass off any obscure and unintelligible matter of pathology, for which more definite terms will give no quarter. If a case presents itself with bold and positive features, such as pain, convulsion, deli-

rium, palpitation, jarring pulse, and highly disordered function, but without certain characteristics of inflammation, it is distinguished by some as irritation; whilst others use irritation and inflammation almost as synonymous terms. If a person faints or dies under a surgical operation, or from a crushed limb, without hemorrhage, the result is ascribed to irritation: in another example, after the same accident, or the same operation, fever arises, and the patient dies in raving delirium; yet this is also termed *irritation*.

We do not venture to impugn the high authorities that have rendered the term conventionally applicable to such varied and opposite affections; but we would warn the student not to be misled in his reading, by the etymology of the word; nor to suppose that in the extended application which it has received from various writers, irritation means anything more restricted than a class of morbid states of very considerable variety.

In further illustration of these remarks, and as an introduction to this subject, we shall extract some account of the views of *irritation* from the works of two distinguished writers, M. Broussais and Mr. Travers.

M. Broussais ("Examen des Doctrines Médicales," and "Histoire des Phlegmasies Chroniques,") bases his description of irritation on the particular physiological views which he entertains respecting the vital properties of animal structure. These properties he calls sensibility and contractility; they are possessed in various degrees by the different tissues, and may be locally increased by certain circumstances; such local exaltation always causing a diminution or depression of vitality in some other organ or system. This exaltation of vitality is accompanied by an excessive afflux or congestion of fluids to the part, and constitutes what M. Broussais throughout his writings designates as *irritation*. The cause or circumstances which produce irritation are of four kinds: —1. Excessive excitement by certain agents, called stimulants or irritants, directly applied; 2. sympathy with another irritated organ; 3. the absence of a stimulus which is habitual to the part; 4. repulsion of excitability from other part or parts.

One of the most remarkable features of this doctrine is, that irritation, when once formed in any part of the system, becomes a cause of irritation in other parts or systems; the influence being propagated by sympathy through the medium of the nerves. The phenomena of irritation vary according to the part which it affects, but the afflux of fluids or active congestion, is common to all primary irritations, and this is prejudicial to the functions and regular nutrition of the part. The first seat of irritation is acknowledged to be in the nervous fibrils of the irritated part; and even in this stage irritation may be so intense as by means of the sympathetic effects on the system to cause death. But M. Broussais looks to the effects on the vascular system as the most important; and if he does not in his pathology describe irritation as vascular universally, his therapeutics certainly imply this; accordingly the terms irritation and inflammation are used indiscriminately throughout his works. The irritation may be confined to the white vessels only, and then he designates it a *sub-inflammation*; but this, as well as what is generally understood by inflammation, is included under the general term irritation.

The increase of sensibility and contractility implied in irritation is sometimes shown by pain, convulsion, &c., but it is not always directly manifest, and is frequently not so, when irritation has its seat in the viscera, where a system of nerves exists which do not transmit sensations to the sensorium. Frequently the sympathetic irritations are more manifest than the original one that excited them. These secondary irritations or sympathies are of two kinds, organic, and those of relation. The organic consist in organic phenomena, such as increased action, congestion, disordered secretion, nutrition, temperature, &c. Morbid sympathies of relation are shown by pain, convulsions of the voluntary muscles, and mental derangements. Any of these kinds of sympathy may be excited separately, but they more commonly coexist; and in proportion to their intensity and number will be the severity of the disease; these generally depend on the sensibility of the organ primarily irritated, and of the system generally. Sometimes the original irritation continues to be predominant; the organ which it affects being the only one to suffer from congestion and disorganization; but occasionally it happens that a secondary irritation becomes the principal; this constitutes *metastasis*. Again, the principal irritation may be transferred to some organ of secretion or exhalation, and is relieved by a discharge from the system; this is what is called a *crisis*. When irritation causes an accumulation of blood in a tissue, so as to produce swelling, redness, and heat, it is called inflammation, this being only an irritation of an intense kind, observing the same laws as irritations in general, except that when unrestrained it proceeds more speedily to disorganization. These appear to be the main features of M. Broussais' doctrine of irritation in general. In describing its further application to particular diseases, he generally uses the terms irritation and inflammation as synonymous, and ascribes to such an affection variously multiplied by sympathy and reaction, and occupying various seats, all febrile diseases, hemorrhages, profluviæ, morbid growths, most of the nervous diseases, dropsies, and even occasionally scurvy itself. In all febrile diseases and considerable inflammations, the heart is sympathetically irritated, whence the quick pulse and hurried circulation; but the main and most important seats of irritation, either primary or sympathetic, are the mucous membrane of the stomach and bowels, and the brain. In all fevers called idiopathic, these irritations are the primary evils: they are equally so in the exanthematous and some other diseases; and there is not an inflammation of an extent sufficient to quicken the pulse which does not sympathetically produce a decided irritation of these organs. The cerebral irritation is in most instances secondary to that in the stomach and bowels, and it always reacts on and increases the latter.

Without proceeding further in the details of this doctrine, which Coutanceau has well named the doctrine of irritation, we may sum it up by saying that there is not a disease to which the human body is liable which is not dependent more

or less directly on irritation. Such an excessive generalization, it might be expected, would have been confined to the name only, and although it should give a new aspect to pathology, it could hardly be anticipated that a corresponding innovation would have been extended to therapeutics. But the case is far otherwise. Broussais, in ascribing all diseases to irritation, and in viewing in that irritation nothing but a grade of inflammation, recognises truly curative means only in antiphlogistics, and denounces all other descriptions of remedy as irrational and hazardous. Nor is he less exclusive in his catalogue of antiphlogistic remedies: purgatives and emetics he prohibits as dangerous *irritants* of the gastro-enteric mucous membrane, that soul and focus of all sympathies: diuretics *irritate* the kidneys; expectorants the bronchial membrane: diaphoretics the skin; and instead of counteracting the original disease, they may reflect on it a new and aggravating irritation: the same objection applies in most instances to blisters and epispastics in general. In short, the whole class of antiphlogistic measures is, with trifling qualification, reduced to bloodletting, abstinence, and dilution.

Whatever may have been the triumphant proofs of success appealed to by the sanguine advocates of this doctrine, we refer to the united experience of the enlightened practitioners of this country, we refer to the records of these pages, for abundant evidence that its absolute practical application would be dangerous and unnatural, and that to deprive medicine of the agents that it so sweepingly proscribes, would be to curtail the art of its most salutary aids. Nothing can more strikingly expose the danger of excessive generalization than a familiar and unbiassed study of nature in all the varieties of her powers; and in our opinion the philosopher who would ascribe all natural phenomena solely to gravitation or some such general power, would not be more partial and incomprehensive in his views than the physician who attempts to restrict the still more complicated and diversified derangement of the animal body to an acknowledged but ill-defined principle, and to still further limit the practice of his art by a partial view of that principle itself.

Great credit is due to M. Broussais for having fully established the fact, hitherto but little noticed, that local inflammations, particularly in the stomach and bowels, are present in most febrile diseases; that such inflammations are capable of producing great disorder and even inflammation in remote organs, by sympathy through the medium of the nerves; and that similar affections frequently complicate themselves with and aggravate many chronic diseases. The most salutary results have been obtained from the application of this knowledge to practice, in the judicious use of adequate antiphlogistic measures wherever these inflammations subsisted; and a more qualified and cautious prescription of purgatives and other medicines in similar cases is another good flowing from the same source. But to make the word *irritation* the representative of the origin of almost every disease; to exclude from pathology all views of general morbid states, whether of plethora or inanition, excitement or depression; to refuse to acknowledge in local diseases any diversity of *mode* of action, referring all morbid phenomena and products only to excess or diminution; to exclude from therapeutics the whole class of alteratives, and to exaggerate in numerous kinds of evacuants their stimulant (often unproved) above their evacuant or antiphlogistic effects: to disregard the operation of narcotics, antispasmodics, and other medicines which exert a direct influence on the nervous system, and through it often favourably affect the vessels;—this is to deny ourselves the advantages of daily experience and unbiassed observation, and to render us the slaves of a system instead of the followers of nature.

If M. Broussais were a little more impartial and considerate towards his own principles, and would take more into view that state of the *nervous system* which he acknowledges to be primary in the state of irritation, and which, as existing alone, may properly be viewed as an object of distinct and specific treatment; if he would admit that a certain state of the vascular system is required before the irritation can produce inflammation, and that, therefore, antiphlogistics are indicated only when this state is present; and if he would take into consideration the secernent and exhalant power as well as the inflammability of the vascular system, and recognise the salutary operation of certain alterative, evacuant, and astringent medicines; then his physiological system would stand on a broad and comprehensive basis, and its application to practice would be consistent both with principle and with the general experience of the most successful practitioners. But in its present state we cannot but view this doctrine as partial and exclusive: and we would decline his use of the word *irritation* as vague in pathology, and fallacious in therapeutics.

The sense in which Mr. Travers uses the term is considerably different, but as he does not attempt to give a definition of it, it is difficult to render in a few words an explanation of his views. He seems to apply the name irritation to any disorder of sensation or function, whether of the nature of depression or excitement, that is not attributable to inflammation or to injury of the mere mechanism of parts. It is chiefly through the nervous system that the phenomena of irritation manifest themselves; and this constitutes the character which most distinguishes irritation from inflammation: but the relation of these two states of disorder must be as intimate as the connection between the nervous and the vascular systems is close and reciprocal. But it will, perhaps, more nearly represent Mr. Travers' view of irritation to say that it is a morbid modification of the irritability of a part or system. Here we are naturally led to inquire what *irritability* is, and what is its healthy proportion and mode of action. Of irritability it can only be said that it comprises the vital properties of a part or tissue, and is shared in various proportions and forms, by the different organs and texture of the body. If there is any rule observed in the distribution of this natural irritability, it is not in the ratio of sensibility, vascularity, or muscularity, but rather according to the importance of the organ in the functions of life. It is much more largely possessed by some individuals than others; and various circumstances, external and internal, are capable of producing a great variety

in its proportion in the same individual. An excess or deficiency of natural stimuli, or the operation of noxious agents, will convert healthy into morbid irritability; and again, if the share of irritability possessed by an organ be morbid, natural stimuli will produce irritation. Thus an irritable stomach may be nauseated and disordered by many ordinary articles of diet; an irritable bladder is continually parting with its contents before the stimulus of distension can be supposed to act: an irritable heart becomes tremulous and palpitating whensoever its action is excited; an irritable skin breaks out in a rash from many slight causes of excitement both of diet and temperature. The description which Mr. Hunter gave of irritability in a morbid sense, "over-action to the strength of the parts," and an irritable habit defined as "an increased disposition to act without the power to act with," accord with Mr. Travers' views of the subject, which are further exhibited in the following passage: "Extreme susceptibility and consequent over-activity are invariably coupled with and most probably dependent on weak and insufficient powers of constraint and resistance. The same principle which renders a part over-irritable renders it over-active. The balance of the system, adjusted by the state of even health, is disturbed by the preponderance or deficiency of either of its active functions, as by the imperfection and disease of either of its organs. A weak organ or constitution is one easily put out of order, because it is continually excited to greater activity than it has power to support,—greater, therefore, than is consistent with the harmony of the system. But action may be morbidly excessive or deficient, independently of organization; and this irregularity, although occasional at its commencement, may become habitual. A too irritable, nervous, or vascular function is, therefore, as marked a constitutional peculiarity as irritable lungs or skin. In a physical as in a moral sense, every individual has a weak part, and this observation would as often apply to the function as to the organ. Circulation, or respiration, or nutrition, in one or other of their many intricate processes, is below par in tone. The absorbent capillary function is below par in scrofulous habits, the arterial in the leucophlegmatic, the venous in those disposed to local congestions; the exhalant in the dropsical; and the pulmonary, gastric, hepatic, and renal, are respectively the failing functions in persons who eventually become the subjects of asthma, gout, jaundice, and stone." (On Constitutional Irritation, p. 15.)

This quotation, although referring only to susceptibility of irritation, will be sufficient to show the extensive view in which Mr. Travers applies the term under consideration. Irritation in this sense cannot be defined otherwise than as a disorder arising from a want of balance of functions. But as no disorder can exist without more or less of a loss of balance of function, it is obvious that there is nothing in this definition which can distinguish irritation from disease in general. It is, in fact, more according to their causes than by any common character in their symptoms that Mr. Travers groups the cases of disease as instances of irritation, and this is perhaps (especially as far as it relates to surgery) the most practical method of arrangement.

Irritation may be either local or general; that is, one or more organs or parts may be its seat, without the rest of the body partaking of the disorder, in which case, it is local; but when the principal functions become affected, the irritation may be called general or constitutional. Local irritation may sometimes become extended to the system, and thus become constitutional; this occurs in cases of severe external injury or disorganization, such as extensive burns, compound fractures, &c. Mr. Travers makes a further division of cases of constitutional irritation into two kinds, direct and reflected. Direct irritation is that wholly and immediately derived from a local source of irritation, the constitution having no share in its production, and is, therefore, proportionate to the local cause. Reflected irritation, on the other hand, originates in a peculiar morbid state of the constitution, is purely idiopathic, and being oftener the cause than the effect of local disordered action, is seldom influenced by local treatment. The symptoms characterizing direct constitutional irritation, are, in the nervous system, rigor, delirium, convulsion, coma; in the vascular, the fever of phlegmonous, suppurative, ulcerative, and gangrenous inflammations. Those which belong to reflected constitutional irritation are, in the nervous system, epilepsy, tetanus in all its modifications, and other anomalous forms of spasm, mania, &c.; in the vascular system, the fever accompanying erysipelas, scrofulous and carcinomatous inflammation, carbuncle, &c.

The division which Mr. Travers has thus made, appears to be abstractedly just and natural, and in extreme cases it is sufficiently easy to distinguish between the local and the constitutional origin of disease. But the more numerous cases of a mixed description, where sympathies and reactions are multiplied and complicated, and where local disease and a disordered constitution affect each other with equal or balancing forces, will seldom bear an exclusive reference to either of these divisions, and it would be unsafe to found practice generally upon them. They are unquestionably more applicable to surgery than to medicine; and it may be said that a principal part of the *medicine of surgery* consists in a due apportioning of the treatment between the local and the constitutional disease. The enumeration of symptoms, which we have quoted above from Mr. Travers' work, would give to the word irritation nearly as extensive a sense as that in which it is accepted by M. Broussais, since inflammatory and all kinds of symptomatic fevers are included under it, and, physiologically speaking, they are so with great justice; but in a practical point of view, seeing that these affections, whatever share irritation may have in them, have their distinct names, and their peculiar and varied forms of treatment, it would seem to us more desirable to limit the term irritation to those affections which partake of the character of excitement or increased vascular action, without the precise characters of fever and inflammation. Irritation undoubtedly attends all inflammations and fevers, but then its phenomena merge in those of the phlogosis or pyrexia, which in a specific and peculiar manner modify the course and determine the issue of the malady. Constitutional irritation is a state so

distinct from inflammation, that it has been remarked, and very justly, that in its characteristic form it is incompatible with it; the former ceasing to exist when the latter is established. It must, however, be admitted, that these two states pass into one another by gradations that it is often impossible to distinguish. Irritation may be considered to be the introduction or preliminary state to inflammation: it is the mobile part of it, and being transferred from one locality to another, draws the phenomena of inflammation after it. But it may exist independently of inflammation: certain additional circumstances are required for the production of the latter; if these are wanting, and the source of irritation still exists, a variety of phenomena ensue, expressive of excitement and disorder of function. What these additional circumstances are, we cannot absolutely specify; but a certain degree of plethora and power in the vascular system are elements which seem to be required before irritation can produce a true inflammation. It is such a plethora and susceptibility of the vascular system which constitutes the phlogistic or inflammatory diathesis; and where this is strong, irritations even of a mild nature may readily become extended to the vessels, and pass into inflammation. Where, on the other hand, the vascular system is ill filled and of low power, any irritating cause failing to excite it to inflammation, develops its effects in various other modes, such as disorder of sensation, secretion, and other functions, the nervous system being apparently the medium through which the irritating influence acts. Between the states of pure irritation and perfect inflammation there are, however, numerous intermediate gradations, in which the phenomena of irritation beyond what usually accompany inflammation manifest themselves, and prove, even in disorder, an unequal balance in the systems. So general is this fact, that there is not a malady of any kind in which more or fewer of the signs of irritation are not *occasionally* apparent, and the history of irritation in this sense would extend to varieties of the whole catalogue of diseases. Such a view would be far too extensive for the due limits of this article. We shall, therefore, merely give a sketch of the pathology of irritation in general, and conclude by a notice of the most remarkable examples of the different kinds of irritation.

Of Irritation in General.—The introductory view which M. Broussais gives of irritation, is far less objectionable than the indiscriminate and unqualified application to which he afterwards extends it; for truly, the reference of disease to changes in the physiological properties of tissues, if unbiassed and comprehensive, is, as far as diseases of the solids are concerned, a fair and natural basis of pathology. But to specify contractility and sensibility as the only properties of tissue, appears to us to be too hypothetical to be admitted as the ground-work of a doctrine; and as there is no necessity for analyzing functions, it is better to treat them simply as they present themselves. Neither are we inclined to adopt the dogma of M. Broussais, which is only a modification of that of Brown, that there is always an equal quantum of excitability in the system, and that an increase in one part necessarily produces a diminution in the other, and, therefore, that there is no such a state as general asthenia or as general excitement.

The functions of animal structure are relative; certain circumstances excite or increase, and others diminish or depress them: exciting agents are called stimuli or irritants; those which depress are called sedative. The relation of an irritant to a function is *irritation*; but the signification of the word here is twofold, for it implies, 1, the agency or act of irritating; 2, the effect or the excited state of the function. It is not unimportant to observe this distinction; and as the construction of our language does not admit of it in the word itself, we shall endeavour to restrict *irritation* to the latter meaning, and describe the other as the *irritating influence* or *act*. Without attempting to explain them, it will be convenient to represent the living properties in general by the word irritability, which merely denotes their relation in the abstract to irritants. There is a certain share of irritability natural to the healthy state of every part, and the moderate operation of natural irritants upon this, constantly induces that degree of irritation which constitutes healthy function. Irritation in a morbid state implies excess, which, when great, sufficiently declares itself by the disorder or loss of balance that ensues; but in smaller degrees, morbid irritation is as hardly discernible from healthy as slight disease is from health.

Irritation may arise from an excess of irritability in a part independent of external circumstances, so that the ordinary or habital stimuli become irritants; or it may proceed from an additional irritating influence from without. Thus vomiting is a symptom of irritation of the stomach: and it may arise from excessive irritability of that organ, as in gastritis, and in the sympathetic irritations of the stomach from concussion of the brain, diseases of the urinary organs, pregnancy, &c.; it may on the other hand proceed from the additional irritating influence of an emetic or of indigestible food. So, likewise, irritation of the mucous membrane of the lower intestines may manifest itself by diarrhœa; and this irritation may proceed from the over-irritating quality of the contents of the intestines as in bilious diarrhœa, and the operation of a drastic purgative, or from the excessive irritability of their membrane, as in dysentery, lientery, &c. Again, the urinary bladder shows signs of irritation when subjected to the unusual stimulus of gravel or stone; and the same phenomena are presented when, either from disease in its coats or by sympathy with some adjacent parts, as in stricture of the urethra and rectum, scirrhus uteri, ascarides, &c., the irritability of the bladder is inordinately increased, and it is continually parting with its natural contents. This division of the modes of irritation is useful, inasmuch as it points out a distinction which is sometimes of the greatest importance in practice, but it is one that cannot always be made; for the two modes frequently unite, and an excessive irritating influence very commonly induces an unnatural irritability of the part to which it is applied. Thus, after an emetic or other irritating substance has been rejected from the stomach, the organ continues for a while morbidly irritable, and refuses to retain the blandest liquids; and the blad-

der often remains irritable after all the gravel has passed away. Again, when the irritability of a part is low, what is commonly an irritant may fail to produce irritation. Thus an emetic sometimes fails to excite vomiting; crude and indigestible food may pass through the stomach, and fæces may accumulate in the intestines without injury; worms may inhabit the viscera, and gravel lie in the bladder, without any remarkable signs of irritation in the respective organs. The same remarkable difference in the susceptibility of irritation is observable in the same individual under different circumstances, and even simultaneously in different parts of the same system. To say that this susceptibility of irritation depends on the degree of sensibility is only to adopt another mode of expression without making the matter more plain. It is generally under the influence of a new or additional irritation that a part becomes awakened to the presence of irritating matters of which it was before insensible. Thus an inefficient purgative frequently develops the irritating influence of fæces long accumulated in the cells of the colon; an excess of diet renders the urinary bladder sensible of the pressure of a calculus hitherto latent; a fit of indigestion occasions irritation of a tumour or other organic disease in the brain to produce a fit of epilepsy. But it is through the medium of the nervous sympathies, which produce what is called constitutional disturbance, that local sources of irritation are most frequently excited. Any thing that disturbs the balance of the functions in general is sure to be felt in the weak or disordered part; and a cause of irritation, which may be long latent during the quiet and equal action of functions, is thus called into activity by any general exciting influence, and, if extensive, often reacts with great energy on the constitutional disease. Again, a local irritation frequently extends itself to the various functions of the system, generally affecting them irregularly and singling out a weak organ, which becomes a new seat of irritation, whilst the original evil receives back with interest, by the same channels of sympathy, the disturbing influence that it had engendered. This interesting subject has been ably treated by Abernethy, Travers, and other eminent writers on medical surgery; and its importance is generally admitted in modern practice. We here allude only to its principle, which is not dissimilar to that of the cases already noticed.

We have hitherto represented irritation as the result of a stimulus or exciting influence, whether the undue relation reside in the irritability of the part, or in the external influence applied to it. The nature of this relation is necessarily obscure, as it is involved in the mystery of the properties of organized matter; and we must therefore at present rest contented with observing the fact. But there is another source of irritation which it is important to notice, equally proceeding from the operation of a prevailing law of organized structure. There is in the living powers a kind of resiliency, or disposition to reaction, which manifests itself after the application of any influence that tends to depress or destroy them; this property often converts sedative into indirect irritants. Thus cold is in itself a sedative; but the reaction, which succeeds to its application, renders it a fertile source of inflammation and irritation. The worst mechanical injuries and severe burns and scalds are likewise sedatives in their immediate effect; and when extensive, this is sufficiently apparent in the syncope, suspension of sensation and function, and even death, which they occasionally produce. There are many instances on record of death supervening on severe accidents, such as the crushing or tearing of limbs, compound fractures, violent blows on the head, epigastrium, or thorax, &c. in which it could not be ascribed to loss of blood, or mechanical injury of any of the vital organs. The death of patients under severe surgical operations without hemorrhage may be attributed to the same cause, assisted often by the powerfully sedative influence of fear and pain. A remarkable and instructive illustration of the influence of mechanical injury may be drawn from the experiments of Legallois, Wilson Philip, Magendie, and others, in which it appeared that violent and extensive injury done to the brain and spinal marrow of animals caused an immediate cessation of the action of the heart, whilst the removal of the whole or any part of these organs in a state of integrity produced no such effect. Bruising or roughly lacerating the brain, or forcing a coarse instrument into the spinal marrow, seemed in these cases to exert a positively noxious and sedative influence on the heart. A more intelligible cause of prostration is loss of blood; but this, although it certainly is so when syncope and death are its immediate consequence, is not, as we shall presently see, so complete and general a sedative as some of the other influences which we have named. Other evacuations and privation from food are essentially of the same nature, but the gradual manner of their operation gives occasion to various signs of reaction, which disguise their direct effect.

The immediate operation of all these causes (and they constitute a most numerous class, for contagious effluvia, malaria, septic and other pestiferous influences may be added to the list,) is unquestionably sedative, or that of prostration; and if the powers of the system should be insufficient to resist or rally from it, they succumb under it. This is the very reverse of irritation, yet, strange to say, it has been commonly confounded with it; and it is when applied in this way to such opposite affections, that the word has lapsed into an indefinite acceptation. If the powers of the system are not subdued by the prostrating or sedative influence, there will then be reaction, in which they usually tend to pass the limit of moderation and regularity, and irritation and excitement ensue in the functions, various in kind and degree, according to the share of power which they severally retain. This appears to be a general rule in the animal economy, and we are not required to go further for an explanation of the reaction which forms a prominent part in many diseases. This reaction may be partial and injurious, as where it displays itself in convulsions, vomiting, hiccup, palpitation, cramps, &c. These symptoms have been called indications of prostration, and so perhaps they may be admitted to be with regard to the system at large, but certainly not in respect of the organs which they affect,

in these they are unequivocal signs of excitement or increased action. They are proofs of impotent and indiscreet reaction, and if not seconded by a reanimation of the organs more immediately concerned in the support of life, they exhaust the excitability of the system, and accelerate the extinction of life.

Another remarkable symptom of reaction is rigor. The addition of this sign to those already mentioned implies a greater degree of power in the system; and in many instances it precedes the development of the highest degree of reaction. Thus it is the first sign of fever, in which it is followed by a series of irritative movements of an intense and general kind. On the other hand it is the symptom of healthy and moderate reaction from syncope; and it frequently succeeds to the sedative impressions of cold without any violent irritation ensuing. It may be represented to be a slight convulsive motion, the object of which is to give an impulse to the circulation of the surface. When reaction becomes more general and perfect, it verges on fever, which may be inflammatory or nervous, according to the prevailing strength of the sanguiferous or the nervous system. But it is to the degrees short of fever and inflammation that we here restrict the application of the term irritation, and in these we find many, but not all, of the functional disorders which attend fever. There is a marked perversion of the functions of circulation, respiration, and digestion. In the former we see a quickened and irregular pulse, with deficiency of force and firmness in the heart's action; whilst alternations of pallidity and flushings betoken an equally irregular tonicity of the capillary vessels. The breathing is anhelatory and distressed; and this sometimes depends on the irregular state of the circulation, and sometimes on the irritation affecting with spasm the bronchial muscles. The powers of digestion may be often said to be almost annulled; a total inappetency for food marks their defect; and we need only allude to the loaded state of the tongue and to the vitiated excrements, as a presumptive proof of the existence of an adequate cause in the depraved state of the visceral secretions. The sensorial functions are likewise variously affected by any irritation extensively present in the body. The sensation and perceptions are commonly exalted and acute, while the other mental powers are below par; hence an irritability of temper and depression of spirits are generally observed; and the loss of balance sometimes amounts to delirium, which is usually of the morose or angry kind.

In the various symptoms that are thus presented in diseases of irritation, we should err were we to expect to trace constantly the features of excitement. It is the loss of balance which is most apparent; and although there must be some undue and misdirected excitement or irritation in some part of the system, the remaining functions will generally (but not necessarily) suffer from prostration and weakness. The more general states of fever and inflammation, through the vascular system which they essentially affect, in their marked and acute forms, entail irritation and excitement of a more equally diffused kind; but irritation, as we consider it, may be confined to a function or organ, while the remainder of the system is suffering from decided asthenia. Thus the stomach and bowels may exhibit irritation in profuse secretion and inordinate movements, whilst other secretory and motory organs are in a state of complete inactivity and prostration. The mamma and the testis sometimes present a form of irritation in an excessive sensibility or constant pain, without any apparent excitement or weakness in their vascular structure. It is in fact a degree of relative, not absolute weakness, that characterizes irritation through all its range of degrees. The excitement takes effect partially only, and the parts unaffected do not contribute to carry the orgasm through a series of processes by which it is at length exhausted, as in the case of inflammation; but if the cause continues, the irritation may persist for an indefinite time, occasioning more or less mischief and disturbance, according to the importance, in the system, of the balance which it destroys. In the greater number of instances of irritation, the vital powers are enfeebled; and this constitutional weakness is the reason why the excitement does not become general and pass to the state of fever or inflammation; but absolute debility is not essential to the existence of irritation; since the most perfect inflammations and sthenic fevers commence with simple irritation, and this is a stage in all cases of reaction. The persistence or protraction of irritation certainly implies relative, and in most instances, general weakness; for the existence of power would lead either to general reaction and restoration of balance, or to the more powerful process of pyrexia and inflammation. The operation of the morbid virus received into the system through wounds in dissection strikingly illustrates two modes of irritation. Its local effect is that of direct irritation, while its action on the system is that of powerful prostration, against which the feeble and irregular reaction of the vital forces develops another kind of irritation. If in such a case inflammation begins in a part, it seldom exhibits the vigorous and decided character of healthy inflammation; but occupying the capillaries principally, and unseconded by any energetic action of the other parts of the vascular system, it takes on an erythematous form, while the effusions are serous or sanious, destitute of coagulable lymph, the plastic effect of which tends to limit and restrain phlegmonous inflammation. The variety of signs which this complication of disorder may present is very considerable; but they principally depend on these two causes—the noxious or sedative influence of the poison, and the irritation resulting from an imperfect and irregular reaction of the vital powers against it. For a full and interesting detail of examples of this kind, we must refer our readers to the work of Mr. Travers, before quoted.

We may, in conclusion, sum up the kinds of irritation under three heads:—

1. Those caused by *direct* irritants or stimuli, whether acting immediately on the part, or mediately through the nerves.

2. Those caused by a preternatural irritability, which, independently of any new exciting influence, renders the relation of ordinary circumstances a source of irritation.

3. Those caused by *indirect* irritants, or those

influences which, although in themselves prostrating or sedative, become irritant through the reaction of the vital powers against them.

This division must be admitted to be in some measure artificial, inasmuch as few examples of irritation occur in which one only of these kinds of causes prevails. They, particularly the first and the second, frequently become engrafted on one another, and occasionally all coexist; but still the greater number of cases are sufficiently stamped by the prevalence of one or other of these kinds of irritation, to render the distinction available in practice.

1. **Diseases of Direct Irritation.**—Of this kind is the disorder resulting from all sorts of slight mechanical injury, whether by contusion, super-extension, puncture, incision, or laceration; from extraneous substances, tumours, effusions, and accidental productions; chemical irritants, too long retained or vitiated excretions; dentition, crudities, and worms in the alimentary canal, calculus in the urinary or biliary passages, and many others. Irritation in all these cases is undoubtedly the result of a reaction of the vital powers, the object of which is salutary, being the removal of an irritating matter or the reparation of an injured part. Whether there be a state prior to reaction which can bear the name of prostration in these cases, as well as in those of the third class, is a matter of merely speculative and not practical interest, since we can detect in their history no other than a direct mode of irritation. The reparation of an injured part depends mainly on the vessels obeying the impulse of irritation: and unless there be a peculiar defect of power in them, the disorder passes into the more healthy state of inflammation. Where this defect subsists, there may be either the imperfect inflammatory action which we see in erythema and erysipelas, or no inflammation at all, and then pain and disordered function or secretion are the signs which attend irritation. It is for the same reason that injuries of tendons, ligaments, fasciæ, and other fibrous membranes, commonly exhibit more of irritation than of inflammation; they are not liberally supplied with vessels, and the irritation, instead of speedily terminating in the reparatory or suppuratory process, lingers longer in the part, with pain, serous effusion, &c., sometimes exciting, sympathetically, severe constitutional derangement, and even tetanus. In the irritation resulting from the application of mechanical or chemical irritants, the salutary object of the reaction is more apparent. Thus, if a grain of sand or salt fall on the conjunctiva, the pain and irritation excite a copious secretion of tears, the tendency of which is to remove the offending matter. Mucous membranes, when irritated, throw out viscid mucus to protect themselves. When a thorn or a needle penetrates the skin, an irritation is produced, which tends to inflammation; this by effusion limits the irritation to the immediate vicinity, and by suppuration removes the irritating matters. But, on the other hand, irritation may fail of its salutary end in all these instances. The grain of sand may remain lodged; the mucous effusion be inefficient as a shield; and the vascular power may be insufficient to effect the process of the expulsion of the thorn or needle; and then the irritation becomes a disease of more permanent character. So worms in the intestinal canal will irritate the membrane of the bowels in every variety of way but a salutary one. Thus they may affect the nerves, occasioning by sympathy grinding of the teeth, convulsions, disordered appetite, various pains, palpitation, &c. The vascular system may likewise be excited, and mucus poured out in great quantity, the peristaltic motion accelerated, without dislodging the offending bodies; whence diarrhœa, with tormina, depraved excretions, thirst, atrophy, and other constitutional disorders, may ensue. The same description will apply to scybalous fæces lodged in the cells of the colon. Indigestible food and excessive acid or acrid secretions in the stomach irritate it in a variety of ways: if the sympathies of the muscular apparatus related to it are quick and susceptible, vomiting is excited, and the end of the irritation accomplished. But if these are not sufficiently roused, the irritation will cause other sympathies and uncomfortable feelings, both bodily and mental; whence arise gastrodynia, pain in the chest, incubus, palpitation, asthma, headach, vertigo, hypochondriasis, &c. The signs of irritation may proceed from such a variety of organs that it appears to be in a manner reflected from one to another. Thus irritation in the bowels is transmitted to the brain and spinal marrow, and from thence developes its effects on the voluntary muscles, producing spasms, convulsions, or chorea. If the original irritation persist long in this direction, it may become fixed on the nervous system, and there continue long after the irritating influence has been removed from the intestines; the disorder of the nervous system may then be considered to be of the second kind of irritation, that, namely, of increased irritability. Calculus of the urinary organs frequently produces irritation of a still more disturbing and unprofitable kind, which has worn down the feelings and functions of many a frame. Dentition is another fertile source of irritation in the bodies of sensitive children. As long as this is restricted to the production of a copious flow of saliva or a moderate diarrhœa, it can scarcely be said to be prejudicial; but it not unfrequently amounts to general disordered secretion, wasting diarrhœa, and atrophy, convulsions, and paralysis; none of which effects tend in any intelligible way to promote the progress of the tooth through the gum. Tumours in the brain or spinal marrow may excite epileptic convulsions, chorea, paralysis agitans, &c. Accidental productions, as tubercles, produce various signs of irritation, both local and sympathetic. Thus, in the lungs they occasion cough, in the bowels diarrhœa, &c., whilst their presence almost always irritates the heart and quickens the pulse. Foreign bodies or splinters of bone in the substance of living structure frequently occasion severe irritation, with little or no decided inflammation. It may declare itself by pain and spasm in the part, and in the system by disorder of any of the functions, quickened pulse, hurried breathing, impaired digestion, delirium, convulsions, tetanus. Pus confined within the proper sheath of a tendon, under a fascia, or within any dense and unyielding tissue, may produce similar phenomena.

Such are examples of direct irritation, and many others might be adduced; as the history of numerous diseases, medical and surgical, abounds in instances of the same kind; but we do not profess to enter into details, and enough has been said to illustrate the principle. Nor shall we do more than allude to another important and extensive cause of irritation, which we cannot hesitate to call direct,—inflammation. It is a cause not only sympathetically, or through the intervention of the nerves, but likewise by mere contiguity. Thus inflammation of the pulmonary pleura excites irritation and consequent inflammation in the corresponding part of the costal pleura; and the same thing gives origin to the adhesions observed between the heart and pericardium, and the peritoneum in its various points of contact. The physical nature of this mode of the propagation of inflammation is involved in much obscurity; and although there are not sufficient grounds to identify it with electric or galvanic action, it is obviously something beyond vascular or nervous communication. But through sympathy an organ or part affected with inflammation produces irritation in various other organs; this is fully exemplified in what is called symptomatic fever, which can be referred to no other principle. It is, moreover, especially remarkable in the sympathetic relations which subsist between particular organs, as the mucous membrane of the stomach and bowels and the brain. And here, while we would acknowledge the truth and importance of the views of M. Broussais on these points, we would insist still on the propriety of distinguishing between inflammation and irritation. The secondary or sympathetic irritations may truly pass into inflammation; but they more generally fall short of it, and therefore require a different treatment; and it is a point important to be observed, that instead of being in proportion to the intensity of the primary inflammation, they are often most prevalent when this is very slight. Thus the cerebral and general irritation accompanying well-marked gastritis is considerably less than that which gastric derangement, or what the French call "embarras gastrique," will produce. It would, perhaps, more nearly represent the reality if we say that the sympathetic disorder is in proportion rather to the irritation of the organ primarily affected than to the intensity of the inflammation. This predominance of irritation over inflammation, although occasionally occurring in the robust, is a character more remarkable in individuals in whom the nervous system has the ascendency, whether by natural constitution, or in consequence of the depression of the vascular power by evacuations or inanition. It is thus that in delicate females visceral inflammations are often accompanied by irritation and disorder quite disproportionate to their intensity or extent.

Certain mental emotions are frequent causes of bodily irritation, and they act in a variety of ways. Anger, joy, and surprise, (which act as general stimulants on a healthy body, and if they tend to produce disease at all, it is congestion or inflammation,) when the bodily powers are in an enfeebled state, become direct irritants, and develop that partial and irregular excitement among the functions and sensations which we understand by the word irritation. They exert their stimulant relation almost exclusively on the nervous system, which in this condition of the body has already a disproportionate ascendency, and they may thus greatly increase that loss of balance which is so much opposed to the state of health. Thus we see the necessity of excluding all such influences from those whose functions are in that state of weakness or depression which continually verges on derangement; such are convalescents from fever and other severe diseases. Grief, fear, and anxiety are indirect irritants, and must therefore be referred to the third head.

2. **Irritation from Excessive Irritability.**—We have already adduced examples of this kind in the case of the stomach after the evacuation of an emetic during pregnancy, or suppression of urine, and under the influence of concussion of the brain, and other injuries or shocks to the system. The intestines, when once excited by an irritant, sometimes present a continuance of irritation apparently from the same cause; and the irritability of the urinary bladder is known to be morbidly exalted in the diseases of the adjoining parts. Inflammation is, however, the most common cause of excessive irritability; and it is in some measure a question whether the above examples may not be referred to a state more or less akin to it. But we see parts sometimes remain permanently irritable without any obvious increase of vascularity; and as there is reason to suppose that sensibility is not always in proportion to the number and size of the vessels, it would not seem just to attribute the excessive irritability of an organ always to inflammation or even to congestion. Mr. Travers considers that the irritable joint, breast, testicle, and prostate gland, give no evidence of inflammation. He records instances of irritable breast and knee joint, attributed originally to needles having entered the parts, which continued painful many months after the extraction of the needles, in the total absence of inflammation. The facial nerves in those affected with tic douloureux present examples of excessive irritability; a draught of cold air or the heat of a fire is enough to irritate them and the adjoining muscles into pain and spasm. The bronchial muscles are inordinately irritable in those subject to nervous asthma; and trifling causes, such as the effluvia of a stable, excite them to spasm. Other idiosyncrasies might be quoted in proof of excessive irritability as a cause of irritation. After an irritation has been transmitted for a considerable length of time from one organ to another, the latter sometimes adopts the habit, and continues to show signs of the same disorder after the original irritating cause has been removed. This is instanced in chorea, arising from feculent accumulations or disordered secretions in the intestinal canal. When these have been removed or restored to a healthy condition, the chorea sometimes continues, and can only be removed by remedies directed to those parts of the nervous system in which the irritation has become fixed.

The uterus in the irregular performance of its periodic function, is frequently the seat and focus of irritation. The nervous excitement, or *innervation* as Andral terms it, by which a flow of blood is called to this organ at particular times, may fail

of its purpose, and instead of being relieved by the establishment of the catamenial discharge, displays its effects in the various forms of what is called hysteria. In this there may be or there may not be local plethora; if there be, the fault of relief must be in the secernent vessels of the uterus; but if there be not, the defect is probably in the sanguiferous system, so that they do not answer to the call. Each of these cases has its separate class of symptoms originating in irritation; but as hysteria and other derangements of the uterine function are fully considered under their respective heads, we do no more than name them. Many other examples might be adduced to illustrate this mode of irritation; particularly in that numerous class in which a congestion or increased vascularity is the cause of excessive irritability; but it is unnecessary to go further. It is by producing a state of this kind, that direct irritants may become causes of this second order of irritations. We may remark that many of the following class of irritations might perhaps be referred to the same head.

3. Indirect Irritation, or the Irritation of Reaction. — In developing the principle of this mode of irritation, we have already cited many instances of its occurrence: these may be greatly multiplied, for they are as numerous as the sedative or prostrating agencies to which the animal frame is liable; but it will be sufficient if we notice generally the forms which they most commonly present. There is probably a successive gradation of conditions from the slightest sign of partial reaction from the state of prostration, such as vomiting, rigor, and convulsion, up to a decided and violent reaction, bordering on inflammation and fever. All these we would designate as degrees of irritation dependent on the same physiological principle, and deriving the variety of their aspect from the number and force of the functions which take part in the reaction. We sometimes see it confined to a single organ; thus the stomach shows it by vomiting, the diaphragm by hiccup, the brain by delirium; whilst all other organs may remain in the state of prostration. Of this description is the effect of violent and extensive injuries or burns, and severe operations, in which the powers are almost overwhelmed by prostration, and the partial effort at reaction, instead of counteracting it, contributes to render it complete and fatal. The pulse here is quick and threadlike, the respiration short and suspirious, frequently with a general rhonchus throughout the chest; if there be no delirium, the intellectual and sensitive faculties are in a state of hebetude approaching to stupor; the pupils are dilated, and the eyelids half closed; the countenance pallid or livid; the surface and extremities cold; the secretions, if not suppressed, are unnatural; and the sphincters often fail in their office. All these are signs of direct prostration, and among them the irritation of reaction may declare itself in a solitary symptom, and in none more commonly than in vomiting, which is often indomitable to the last, and greatly hastens the fatal event. It seems to proceed from extreme irritability of the stomach, which rejects the blandest liquids. A low delirium, with various hallucinations of the perceptions, may equally accompany this state; it is a sign of the irritation of reaction in the brain, and is prejudicial both in being misplaced reaction, and by leading to bodily efforts which add to exhaustion, and not uncommonly prove instantaneously fatal. Convulsions arise in the same way, and produce similar effects. Such is exhaustion with the lowest signs of reaction. In other cases irritation takes a larger share in the diseased state consequent on the injuries under consideration. Thus, after rigors, the pulse may become sharp and bounding, with throbbing in the head; the eyes glassy, with contracted pupils; the delirium fierce, or there is great restlessness and morbid sensibility: spasms may occur in various parts of the body; there may be pain in all degrees and positions; the heat may be partially increased, although the extremities are generally cold. Here, although beginning in prostration, the chief features of the disease are those of misdirected and excessive reaction. They border very closely on fever and inflammation; and it would be rash to say that they are always distinct from these states: but although the delirium and exalted sensibility are sometimes so marked as to give suspicion of the existence of phrenitis, examination of the brain after death discovers no sign of increased vascular action further than some turgescence of the vessels, which is totally disproportionate to the intensity of the symptoms. Other organs, the lungs, the heart, the stomach and intestines, but particularly the serous membranes, are occasionally the seat of this kind of irritation, which puts on the semblance of inflammation; but less commonly in reaction after local injuries or operations, than after prostrating causes which have a more diffused seat in the system, such as cold, loss of blood, and inanition. The general tendency of all these irritations is to exhaust, and unless controlled and counteracted, they wear down and destroy the remaining irritability of the system, and death necessarily ensues.

It is the continued impression of a sedative or prostrating influence that renders reaction imperfect, and converts it into an injurious irritation. Thus the powers in general may be unable to rally after the first shock of any severe injury or operation; but this inability is frequently dependent on some additional sedative influence, bodily or mental. Fear and anxiety are most powerful in this way; and instances are on record in which operations, trifling and favourable in their surgical relation, have led under their influence to a fatal result. Women have died after successful and natural parturition, barely from the effect of a presentiment that they would die. To such instances cited in Mr. Travers' work before mentioned, he adds a case of the death of a lady after a labour protracted unusually by the evolution of a polypus after child-birth; and another of a gentleman who died in twelve hours after the escape of the contents of the stomach by perforation into the peritoneal cavity—ascribing these fatal events to the sudden, extreme, and unremitting pain: but we question whether they may not be as fairly attributed to exhaustion from muscular effort in the first case, and in the latter to the prostration of the heart's power by the severe and extensive injury to the peritoneum, as in other cases of acute peritonitis. Pain, though commonly at first a

powerful irritant, when exceedingly severe occasions syncope, and by fatiguing the powers otherwise produces a prostrating effect: in this way it will tend powerfully to subdue the disposition to general reaction. It implies the worst species of mental excitement, which entirely prevents the repose essential to restorative reaction; but as we sometimes see the body bear pain even in its greatest degree with impunity, and as we know that a certain integrity of the function is necessary for its continuance, we can scarcely look on it as being ever alone a sufficient cause for fatal prostration. The sedative influence of grief and fear is so decided that they may not only aid other causes, but by themselves destroy by prostration; and this may, as in other cases, be with or without irritative reaction.

But the most remarkable species of causes of irritative reaction are those which depend on inanition, whether arising from bloodletting or other evacuation, or from imperfect nutrition. We owe to Dr. Marshall Hall the first distinct notice of these morbid affections: his observations have been confirmed by Dr. Abercrombie, Mr. Travers, Dr. Gooch, and other subsequent writers; and he has since given a fuller account of them in his "Researches on the Effects of Loss of Blood," a work recording some new facts of great practical importance.

The immediate morbid effect of loss of blood, if extensive, is the same as that of the other prostrating influences which we have mentioned, syncope, coma, convulsions, and delirium. The two latter, although they appear closely allied to the others, we cannot but view as different in their nature, and as resulting either from a partial effort of reaction, or from a remnant of local power, preponderating unduly over general prostration. They most frequently occur where the excessive loss of blood has been gradual, as by atonic hemorrhage, epistaxis, by bloodlettings often repeated, or through a small orifice and in the recumbent posture. The gradual draining of the system in these ways, or by other excessive evacuations, such as continued purging, and by starvation, which have the same effect in the feeble, after the lapse of these symptoms frequently gives rise to a train of signs of irritative reaction of more prominent and decided form. There will be palpitation of the heart, with quick and jarring pulse, and throbbing of the carotids, aorta, and other arteries, and the auscultator will perceive a purring or grating sound in these parts. If this irritated state of the circulation continue, it will induce its effects on the sensations and functions; sensibility will be increased, with intolerance of light and sound, pain, throbbing, and noises in the head, an excited state of the mind amounting to delirium, a loaded tongue, and general disorder of the secretory functions. This condition, which is amply described by Dr. M. Hall in the work before quoted, and in the articles Bloodletting and Abstinence in these volumes, is a fair example of irritation in its characteristic form. Here is great excitement and disposition to act, but no power to regulate or support it: here are the nervous phenomena of inflammation without that permanent and powerful state of the vessels which can lead it to any of its usual terminations. The semblance of inflammation which it frequently presents often induces the practitioner to draw more blood; the evil consequences are sometimes immediate, syncope, convulsions, and death; and when there is a temporary amelioration, it is only a prelude to a worse return of irritative reaction So great is the real weakness in the midst of all the apparent signs of excitement, that the erect posture or any kind of exertion may prove fatal. It may terminate fatally also in a more gradual way, by passing again into the state of sinking or pure prostration; and here likewise it may put on a fallacious aspect in its resemblance to the signs of effusion on the brain. In children particularly, this imitation is so close that Dr. M. Hall has called it the hydrencephaloid disease. In favourable cases irritation terminates in subsidence and a gradual restoration of power, and with it a recovery of balance among the functions. But the irritation may pass into a chronic state, and of this description Dr. Hall considers puerperal mania, amaurosis, deafness, paralysis, &c.

The delirium, mania, and increased sensibility in those suffering from privation of food, recorded in several cases by Dr. Currie, Dr. Latham, Andral, and others, are obviously of the same nature of irritations of reaction; and in the pain of the head and stomach, and irritable state observed in those under the influence of a great and sudden lowering of diet, we see a more familiar illustration of the same kind. Similar symptoms often accompany the wasted and atrophied condition of infants unduly nourished, with whom the maternal milk disagrees, or whose powers of digestion cannot master the food that is given them; and they not unfrequently develop themselves in the asthenia lactantium, and in any form of undue nutrition. For further illustrations, see the articles Abstinence, Chlorosis, and Lactation (Diseases of.)

Treatment of Irritation.—Having described irritation as a general pathological principle rather than as a specific disease, our remarks on the remedial measures calculated to counteract or remove it must be equally in the abstract, and merely illustrated by prominent examples.

The removal of the irritating influence, if possible, is the most obvious indication in the cure of direct irritation; and in the slighter cases this may be a sufficient remedy. Thus, the removal of irritating matter from the stomach by means of an emetic; from the intestinal canal by a purgative; the counteraction of acidity by a dose of alkali; relieving by a stroke of the lancet the tension of the swollen gum in dentition, or of the integuments or a fascia in a superficial or deep-seated abscess, may amount to a complete cure of the various forms of irritation, which these causes severally occasion. But it is not always possible thus to reach the root of the evil; moreover, as we have already remarked, when once planted, the disease propagates itself so as in a degree to become independent of its first cause, and thus to belong to the second class of irritations. Hence it often becomes necessary to combine, with the measures directed to remove the irritating influence, others calculated to diminish irritability; and where the original cause is obscure or baffles our efforts, this is the only system of medication that can be pursued. This combination is the more expedient in intestinal irritation, as the remedies

suited to remove the offending cause in themselves for a time aggravate the irritation. Thus it is proper in such cases to give before or with the purgative some narcotic, such as hyoscyamus or opium, and further, if necessary, to allay the irritation of its operation by diluents, the warm bath, and other derivants. It is not easy to lay down any rule by which the relative importance of these measures can be decided; but the sedative plan is generally more requisite in proportion to the length of time and the degree in which the constitution has suffered under the irritating influence. Where the irritation is vehement, and disturbs in a serious degree the vital functions, it becomes of more importance immediately to allay this by temporising measures, than to rest solely on those which are more radical, but of slower operation. A child suffering from worms or accumulated fæces may die of convulsions under the additional irritation of a purgative before its evacuant effect can be obtained; but if this medicine be preceded by or conjoined with others calculated to soothe, such as hyoscyamus, Dover's powder, or the warm bath, according to the character of the irritation, its operation will be safe and seasonable. The purgative is, moreover, by the same means, often rendered more effectual for the removal of the irritating matter, since its slower progress enables it to act more generally on the canal, than where an excessive irritability hurries it precipitately through. So also, during the prevalence of violent spasm, an antispasmodic must often be promptly administered without regard to the duration of its effect. To give ether, laudanum, assafœtida, valerian, &c. in spasm of the glottis or bronchi, or in violent palpitation of the heart, may be, in relation to the cause of the irritation, a temporizing measure; but it is using time to good purpose.

We have enumerated inflammation among the causes of direct irritation, and we again allude to it for the purpose of remarking, that besides the removal of the cause itself, our attention may sometimes be usefully directed to the quieting of those nervous sympathies by which the irritation is communicated to the system at large. This, we apprehend, is the principle of the salutary operation of opium in continued fevers and the less sthenic forms of inflammation; and did we possess a medicine that should be sedative to the nervous system without exciting or disturbing the vascular, it would furnish a still happier and more satisfactory illustration.

There are many cases in which the source of irritation is organic, or beyond the reach of remedies; it is thus with tumours in the brain, spinal marrow, and other parts, accidental productions, cancer, and other forms of diseased structure; here our only resource is in measures which allay morbid irritability. We shall have occasion presently to revert to this subject; but we see no need to dwell longer on means for the removal of irritating influences: they vary with the nature and locality of the influence.

There is another mode of treating direct irritations, which it may be convenient to notice in connection with direct irritation, although it is more frequently applicable to the indirect kind, namely, by stimulating applications. In enumerating examples of direct irritation we named various mechanical injuries, and remarked that the object of irritation in these cases, the reparation of the injured part, is sometimes defeated, and the disorder prolonged in consequence of the low power in the vascular system, which is inadequate to take on the reparatory state of healthy inflammation. Here, then, an additional stimulus to the vessels, conjoined, if need be, with a sedative to the excited nerves, will often recall the irritation from its prejudicial wanderings through the system into a local and salutary channel. This treatment is obviously applicable only in cases where inflammation is not in itself a hurtful process, such as mechanical injuries and sores of the exterior, and especially burns and scalds. The efficacy of stimulating applications to the latter is now generally admitted, and we would attribute it entirely to this principle in all the moderate examples of these lesions. The extreme heat has so paralyzed or weakened the vessels, that although they may be entire and congested with blood, they require a new and powerful stimulus to bring them to that activity of function which the reparation of the injury requires. When a part has been disorganized, and is insusceptible of revivification, and the adjoining vessels are weak and inactive, stimulant applications are still more obviously indicated to excite that inflammation which is necessary to effect the sloughing or separation of the noxious dead matter from the living structure. We can see the utility of a similar treatment in other forms of external disease, where the inflammation is at once irritative and powerless.

We have already glanced at the treatment of our second order of irritations, that of excessive irritability, for the mixed manner of their occurrence renders it inexpedient to consider each kind quite separately from the other; but we return to the subject, in the endeavour, as far as is possible, to make this sketch of the principles of the treatment correspond with the preceding pathological history. Excessive irritability, as we have there remarked, most frequently depends on inflammation or some of the states akin to it, or (to use the more comprehensive words of M. Andral) hyperæmia in its several forms. In such cases relief is to be sought in the various antiphlogistic measures, applied of course with due relation to the organ whose morbid irritability is to be reduced; and thus evacuants, derivants, counter-irritants, and contro-stimulants, become remedies for irritation. These are considered in the article Inflammation sufficiently to supersede notice here, further than the remark that their anti-irritant may not always be in the ratio of their antiphlogistic effects; and where irritation predominates over inflammation, those are to be preferred which act on the nervous as well as on the vascular functions; thus, counter-irritants (and if they be admitted as a separate class, contro-stimulants also,) will avail more than mere vascular deplctories in fulfilling the indication in view. For example, in the vehement irritations connected with slight phlogoses of the mucous membrane of the lungs and of the alimentary canal, (notwithstanding Broussais' positive assertions to the contrary,) tartar-emetic frictions for the former, and sinapisms and blisters for the latter, are far more efficacious than local or general bloodletting. The irritations of serous membranes,

which in persons of mobile sensibility frequently present the semblance, although they partake little of the real character, of inflammation, likewise receive most relief from this description of antiphlogistic treatment. The contro-stimulant or sedative influence of cold directly applied is exerted equally on the vessels and nerves, and it would be, doubtless, a powerful means of subduing irritations, were it a more manageable agent; as it is, we see its beneficial influence in the relief afforded to cerebral irritation, and in those of the limbs by applications of ice and cooling lotions. The expediency of using it, (as do the Broussaians) in abdominal and thoracic inflammatory irritations, is very questionable: the risks of repelling the inflammation more inwardly, and of its being aggravated by reaction if the application of cold is unsteady or insufficient, besides the obvious injury to the system of continually abstracting from organs that degree of heat which is almost necessary to their life, are surely sufficient objections against a practice that is far from being generally recommended by the experience of its advocates. External heat, whether dry, as applied by hot flasks, bricks, or air, and acting as a rubefacient, or combined with moisture in fomentations, baths, or poultices, and proving revulsive and sudorific, is a much less exceptionable remedy for internal irritations. In its moderate degrees the latter are more suited to inflammations, as their effect is principally on the circulation, which they soothe and equalize; but in its highest tolerable degree, heat produces a strong impression on the nervous system; very hot flasks, or flannel wrung out of water almost scalding, are among the most powerful of antispasmodics or local anodynes, and we have seen them produce perfect and immediate relief in the irritative pains of colic and dysmenorrhœa, where many powerful narcotics had failed.

As we are now verging on the subject of means directed particularly to lower nervous irritability, we may premise that there are some narcotic or sedative remedies which, if they do not act as such on the vascular system likewise, do not stimulate it; they are, therefore, often admissible in inflammation itself, and are the more strongly indicated when it exhibits the character of nervous irritation. Of these, none for safeness and general applicability ranks before the hyoscyamus. Mr. Travers says, "In the ruffled states of the system generally, but especially in the over-active state of the vascular system, there is a charm in the operation of henbane altogether peculiar. It is feeble as an anodyne, feebler as a soporific, but 'not poppy nor mandragora' soothe and still so unexceptionably as henbane." This remark, although true, requires a comment; the over-activity of the vascular system here alluded to is not one of inflammation, but of irritation, dependent on excess of nervous irritability scattered through the different organic sympathies; and it is in its sedative influence on these that the charm of henbane consists; for it exerts little or no effect on inflamed vessels, that are, as it were, over-active in their own strength. We may almost say that on its little interference with the vascular system its general eligibility depends; for, restraining no secretions, it can advantageously be given alone or combined, without the risk of purchasing temporary relief at the expense of that balance of functions which is so essential to health; and unless where pain and excited sympathies are useful as guides in the employment of more active remedies, there is scarcely an instance of morbid irritation unfitted for its use. The main fault of hyoscyamus is its weakness as a narcotic; it not unfrequently fails of its effect, and, perhaps sooner than other remedies of the same class, loses its power by continued use.

Of the other remedies of this class we may mention favourably conium, belladonna, colchicum, digitalis, and hydrocyanic acid. Their fitness in various diseases is less extended than that of the medicine already named; and it is particularly restrained by their greater liability to disagree with the stomach. The two first approach in their properties most nearly to hyoscyamus. The three others exert a decidedly sedative effect on the vascular system, but rather through an influence on the heart, the force and number of whose pulsations they diminish, than from any action on the vessels at large. Their beneficial effect is, therefore, best seen in irritations of this organ and of the lungs, which stand in so close a relation to the heart. The directly sedative influence of hydrocyanic acid is, however, sometimes remarkably evinced by its allaying the morbid irritability of the stomach; and it is successfully applied externally to allay the irritation of prurient eruptions. Colchicum is supposed to possess a specific sedative power in the irritations of gout and rheumatism. Whether this may depend on its carrying off through the kidneys an irritant matter from the blood is uncertain; but the diuretic effect of this remedy and of digitalis should not be overlooked. Conium and belladonna, when the system can bear them in sufficient doses, are sometimes very beneficial in allaying irritation of the pulmonary system, whether manifesting itself in spasm of the bronchi, or in an excessive irritability of the mucous membrane, exciting cough. The smoke of stramonium and of tobacco enjoys a similar reputation, but it is decidedly stimulant to the vascular system. Poultices of the recent leaves of various narcotic herbs, but particularly conium and belladonna, are very efficient in allaying the irritation of unhealthy ulcers: the leaves of the latter in form of ointment show great power over both vessels and nerves, in relieving and preventing the chordees of gonorrhœa.

We pass over others of lesser note to the chief of narcotics, opium. This medicine, although under certain circumstances the most sure and most powerful of anti-irritants, has so many ulterior effects, that more than any other it requires judgment in its exhibition. Its first effect is to stimulate the vascular system, and this is sufficient to exclude it from all those instances of sthenic inflammation where it is wished to retard or arrest rather than to hasten this process. But in the asthenic phlegmasiæ, especially where nervous irritation predominates, the administration of opium is counter-indicated only by the ulterior effects which it may have in arresting the secretions. Combined with ipecacuanha, with antimony, and especially with mercury, it ceases to be liable to this objection, and its operation is often in the highest degree salutary. Even where

it is wanted as a pure anti-irritant, to reduce morbid sensibility in the nerves, we should always prefer it in combination with ipecacuanha, which seems to equalize without injuring its narcotic virtues; and in further combinations, it is not common to experience from this compound the inconveniences that frequently result from laudanum or opium. The muriate and acetate of morphia, equally with Battley's *liquor opii sedativus*, enjoy the reputation of a purer sedative property than the common forms of the drug possess; but unless where a speedy effect is desired, there are few cases in which we would not place greater confidence in Dover's powder, or tantamount combinations of ipecacuanha and the aqueous extract of opium. It is an almost indispensable adjunct to purgatives in violent gastro-enteric irritation where hyoscyamus would be insufficient; and if the stomach will retain it, it seldom fails to quell the excessive disturbance that sometimes follows drastic and unguarded purgation. In dysentery, and in more chronic forms of excessive irritability of the intestinal canal, the proportion of ipecacuanha may with advantage be doubled or quadrupled, as in the dose of one-fourth or one-eighth of a grain of extract of opium, with one-half or a whole grain of ipecacuanha, repeated according to the urgency of the symptoms.

We must notice a more obscure class of remedies, alteratives, which, whatever may be their mode of action, are unquestionably entitled to a place here. Under this unscientific but convenient title, we reckon the various non-purgative forms of mercury, whether simple or combined with opium, those of antimony and ipecacuanha in acute diseases, and in chronic disorders minuter doses of the same, sarsaparilla, mezereon, chalybeates, and a host of other medicines. The efficacy of the first-named of these in restraining and subduing inflammatory action would obtain for them, among the disciples of the new Italian doctrine, the appellation of *contro-stimuli*; but this, like cutting the Gordian knot, is only substituting a bold stroke of hypothesis for a solution of the difficulty. It is not impossible that tartar-emetic and mercury may exert on the coats of inflamed or irritated vessels such an influence as directly neutralizes or subdues their disorder, and restores their healthy function; but this is a large assumption to take for granted; and in the absence of any sort of positive proof, we think it safer and as philosophical to arrange the remedies in question under the modest title of *alteratives*. These remedies are powerful in subduing irritation; and on the basis of the views which we have given of this morbid state, we might equally well frame an hypothesis that they act by restoring a lost balance, and by equalizing the distribution of natural irritability. But we will content ourselves with remarking the fact, that mercury, antimony, and in a minor degree ipecacuanha, tend moderately and equally to restore all the secretions which inflammation and irritation arrest or pervert; whilst opium, deprived in this combination of its restringent qualities, happily allays the excited sensibilities and sympathies of the nervous system. The alteratives prescribed in chronic irritations, although in greater variety, probably act on the same principle; and, perhaps, the exhibition of what are called alterative doses of blue-pill, Plummer's pill, ipecacuanha, dandelion, and sarsaparilla, and mineral waters in chronic diseases of the viscera and skin, is more generally acknowledged as an appeal to the various secretions.

Before passing to the last class of remedies, tonics, we would advert for a moment to the salutary effect of friction and exercise in allaying morbid irritabilities of a part of the system. They hold an intermediate place between alteratives and tonics, and in affinity with either they well merit consideration. Friction, steadily and moderately applied, is an efficient anodyne. Although injurious in acute inflammations, it allays in a wonderful manner various nervous pains, spasms, and other disagreeable sensations connected with irritation and irregular circulation, and it is a valuable auxiliary to anodyne applications. It is an alterative to the vascular system, inasmuch as it removes congestions and obstructions, and promotes healthy circulation and secretion; and in the regular continuance of these effects by exercise, increased by the contact of pure air, consists the tonic power of these hygeian agents.

The utility of tonics in subduing morbid irritabilities will, if we mistake not, be sufficiently apparent from the pathological views which we have endeavoured to expose. Agents which give tone and strength to the vascular system will destroy the preponderance of that nervous mobility which is the basis of irritation. Under their prosperous influence, disposition and power to act will go together, and within due bounds produce the harmonious balance of even health. Whether certain of them possess a specifically sedative property towards the nervous system, or whether this is their secondary effect after their tonic and astringent influence on the vessels, is beyond our means of decision; but the fact is not less ascertained than important, that the continued use of nitrate of silver or sulphate of copper will cure the epileptic irritations independent of organic cause, and often diminish them where the cause is irremovable, by lowering in the nerves their susceptibility to its impressions. Thus, likewise, bark, carbonate of iron, arsenic, sulphate of zinc, or subnitrate of bismuth, sometimes remove the painful or spasmodic irritations of tic douloureux, hemicrania, sciatica, chorea, and gastrodynia, which the most powerful anodynes, antispasmodics, and counter-irritants fail to effect. The stomach and intestinal canal, likewise, under the influence of a bitter tonic, will often lose various signs of irritation, which, however they may occasionally be accompanied by slight hyperæmia, or fancied inflammations, owe their being to weakness and want of tone. The cold shower or plunge-bath, or cold ablution, is another efficacious tonic; the more eligible, often, because, without loading the system with medicine, it rouses it to the exertion of its own powers in a vigorous vascular reaction, under the habit of which nervous mobility is physically forgotten, and ceases. But it is needless to add to examples which have been adduced only as illustrations of a principle.

We have, finally, to glance at the leading peculiarities required in the treatment of indirect irritation, or that arising in the reaction after prostration. The most obvious indication is to promote

and regulate the reaction, so that it may rise to the point of a general and equal recovery of function, without passing beyond it into a state of irritation or inflammation. The most common state which we have to deal with is that of irregular reaction, local and misdirected excitement amidst general prostration. Whether this excitement consist in convulsion, hiccup, vomiting, delirium, palpitation or cough, it is of the utmost importance that it should be subdued; and to effect this, it is of more avail to direct our efforts to excite the powers generally, by diffusible stimuli, than to attempt to quiet the local irritation by sedatives; for as the other powers rise from the prostration, this symptom will generally subside. But should this not be the case, and the local irritation be wearing down the strength, sedatives must be addressed to it: this part of the treatment will not differ from that of morbid irritability already considered. The point which characterizes the treatment of this form of disease is the necessity for counteracting the prostrating influence which paralyzes the plurality of the functions, leaving others in proportionate predominance. This indication resolves itself into the removal, as far as is possible, of this influence, and the further obviation of its effects.

Cold, and the resulting prostration, are removed by the same means, the gradual and cautious restoration of heat, beginning by frictions with snow, &c. and carefully restraining the disposition which is commonly manifested to excessive reaction; on this account diffusible stimuli are only sparingly admissible. See Cold.

The prostrating influence of a severe mechanical injury, as of a crushed limb or bad compound fracture, seldom ceases on the removal of the limb; on the contrary, the additional shock of the operation not unfrequently proves fatal. The absence of inflammation leaves the system open to the noxious influence of the shattered structure, which inflicts a stroke felt even after its removal. Were healthy inflammation soon excited, this would probably in a degree counteract or interrupt this influence; and we hazard the suggestion that stimulating applications made to the injured part previously to the operation, might, as in extensive burns, be of more avail than mere internal stimuli. The existence of inflammation in the system has been shown by Dr. M. Hall to protect it in a remarkable degree against the prostrating effects of loss of blood, and the same thing obtains in some measure in other cases of prostration; hence asthenic inflammation may be useful not only as proving power in the system, but also as a general tonic, imparting a stimulus to the heart and vessels. This remark is most applicable to surgical cases, in which inflammation is an important and necessary process; but we see in it also an explanation of the utility of artificial inflammations excited by sinapisms, blisters, and stimulant frictions, in failure of the powers from various causes, and in the state of sinking from any severe disease. Any of these measures, as local counter-irritants and general stimulants, often prove beneficial in arresting vomiting, hiccup, convulsions, or any other partial reaction, amidst general prostration. In the worst cases, however, they fail to excite inflammation; for the skin, like other parts, seems to have lost the attributes of vitality.

Of the diffusible stimuli fit to oppose the state of sinking or prostration, the most powerful are ammonia, alcohol, and opium. These are variously applicable, according to the degree to which the depression has extended. Ammonia is the most purely stimulant, and is, therefore, best adapted to cases in which there is least of local irritation, or where this manifests itself in spasms. The complete prostration induced by tobacco, digitalis, and other sedative poisons, and the asphyxia from the fumes of charcoal and sewers, are examples to which the stimulus of ammonia seems to be especially adapted. The carbonate of ammonia is the most common preparation, and it is conveniently combined with alcohol in the spiritus ammoniæ aromaticus, which is the form most agreeable to the stomach. It is to be borne in mind, however, that it is a chemical agent as well as a vital stimulant; and this circumstance precludes its being given to a very large amount. Spirits in the various combinations, brandy, wine, and ether, is a highly valuable stimulant; and it is the one perhaps most to be depended on in general prostration with irregular reaction. It exhibits some narcotic virtue in its property of quieting the irritated sympathies of this state, and is peculiarly serviceable in arresting the severe vomiting which often severely and fatally aggravates various forms of exhaustion. It is of the greatest importance to watch most assiduously the state of a patient who requires a large exhibition of stimuli of this kind, both to ensure their being supplied often enough, which in case of sinking must be done every five or ten minutes, and to diminish or withdraw them the moment they produce an effect on the circulation, lest they stimulate it beyond the point of moderate and general reaction into a state of febrile excitement. Opium, as it partakes largely of narcotic as well as of stimulant properties, is less adapted to the extremest forms of prostration than to those in which the irritability of the system is misdirected. In the state of sinking, when the respiratory function is failing with the rest, opium might have the effect of destroying the sensibilities and sympathies on which this vital process depends. But for the different partial irritations attendant on general weakness, particularly delirium, spasm, palpitation, and hiccup, opium is generally the most satisfactory remedy. Solid opium and its tincture are here the most expedient forms; and their stimulant effect is most fully developed by small doses frequently repeated. If the antispasmodic property is desired, larger quantities must be given; and it is truly astonishing what doses the system will bear when under the influence of spasmodic disease.

The first objects in extreme prostration are, to sustain the functions of respiration and circulation by diffusible stimuli, until there is a sufficient recovery of the forces to support these without further aid. The organic functions of secretion and assimilation then generally require some assistance; for the effects of the depressing influence sometimes manifest themselves on them after the circulation has been restored to some degree of vigour. Here alteratives and tonics come into requisition; and, as in direct irritation, they must

be variously modified and combined, in order to ensure the most equal and natural excitement of the several organic processes. Where the prostrating influence still remains in the system, counteracting vigorous reaction, and enfeebling or paralyzing all the conservative powers, these several remedies must be conjoined. Thus, under the noxious influence of gangrene, asthenic erysipelas, or poisoned wounds, it becomes necessary to administer wine or spirits, ammonia, opium, or camphor, with bark or sulphate of quinine, whilst the secretions are excited by calomel or blue pill. Bark has sometimes a signal power in combating with the depressing influences in question; and its efficacy may, perhaps, depend on the same property which renders it so complete an antidote to the causes of intermittent fevers.

The irritation of inanition, in respect to its symptoms, may require in great part the same treatment as that from other causes; thus sedatives to the nervous system, and the exclusion of all sensorial excitements, will be equally necessary. But the nature of the causes may modify the indications: as they consist in a loss from the system, the necessity of supplying nourishment for the reparation of that loss, giving to the assimilatory organs the aid of additional stimuli, is obvious.

It is necessary to be on our guard against the invitations which these forms of disease sometimes hold out for the use of antiphlogistic measures: these afford but temporary relief to the pseudo-inflammations which arise in this state, and which are more safely and effectually subdued by sedatives, a judicious supply of nourishment, and an exclusion of all exciting or disturbing agencies. Thus we may see a disease following extensive evacuations, which puts on the semblance of violent pleurisy, pericarditis, arachnitis, or hydrocephalus, often completely relieved by hyoscyamus or opium, with a sustaining nourishment, such as sago, arrow-root, or jelly, with small quantities of brandy or wine. The state of the circulation is the safest guide in the conduct of this treatment; as long as the pulse is weak or fluttering, with its quickness, and although sharp or jarring in its first impulse, yet leaves the artery in the intervals empty under the finger, the sustaining treatment must be continued, and local pains, palpitation, disturbance of the mind with beating or noises in the head, viewed as partial reactions, to be subdued by opium or hyoscyamus rather than by the lancet and evacuants. But if these symptoms have been relieved, and the pulse has recovered in a measure its steadiness and fulness, the spirits and other stimuli must be diminished or withdrawn, and the rest of the cure left to time and to whatever alteratives circumstances may suggest. These points are more fully described under the heads of the several diseases connected with this subject, and which have been already referred to.

The prophylactic treatment of those liable to irritations will generally consist of those means which, by giving tone to the vascular system, remove the preponderance of nervous influence or susceptibility. These are tonic medicines and a tonic regimen in general; but if there be already a loss of balance in the vascular system, it will be generally necessary to direct some alterative to regulate it. There are various circumstances of diet and regimen which tend greatly to engender a general morbid irritability; particularly an habitual and excessive indulgence in spirituous liquors, smoking, very strong tea or coffee, and opium-eating; close or crowded habitations, and a sedentary mode of life. Besides avoiding these predisposing causes, those who are of an irritable habit should rise early, and keep regular hours, use exercise in a bracing air freely, but not so as to induce much fatigue, live on food of the most wholesome and nutritious kind, and attend in every possible way to the promotion of equality and regularity of the functions.

C. J. B. Williams.

ISTHMITIS. (See Throat, Diseases of the.)

ITCH. (See Scabies.)

JAUNDICE. (Ἴκτερος, *icterus, morbus regius, aurigo, &c.*) Jaundice is a disease of rather frequent occurrence, characterized by a yellow colour of the eyes, skin, and urine, and by the white appearance of the alvine evacuations. In addition to these general symptoms, the malady is frequently attended with extreme depression of spirits, languor, inactivity, and watchfulness; with a bitter taste in the mouth, thirst, loss of appetite, nausea, or vomiting; a sense of fulness or other uneasiness, if not also actual pain, at the epigastrium; occasional shiverings and profuse perspirations; a distressing degree of itching in the skin, and rapid emaciation. The urine soon becomes of a deep mahogany colour, yet gives a bright yellow tinge to substances immersed in it. The state of the bowels is variable, being in some cases relaxed, in other cases confined, but generally acted upon with facility by mild aperients.

[Dr. Mackintosh (*Principles of Pathology and Practice of Physic*, 2d Amer. edit. i. 431, Philad. 1837,) states, that he has known several individuals affected with jaundice, who saw every object coloured. Most of the secretions are unquestionably tinged yellow, but not all. The colouring matter of the bile is rarely found in mucus or milk, for example. Yellowness of the conjunctiva is, however, one of the pathognomonic phenomena. Bile is, also, necessarily present in the blood-vessels of the retina; yet, as the writer has elsewhere said, (*Practice of Medicine*, 2d edit. i. 625; Philad. 1844,) yellow vision is not common. In the experience of one observer, Dr. J. P. Frank, it was noticed but five times in about 1000 cases. Much difference of opinion has existed in regard to the cause of the phenomenon when it does exist. The most probable supposition is, that the humours themselves are tinged yellow, and it has been suggested, that where vision is not yellow, they may have escaped the tinge. There is some plausibility, however, in the supposition, that tho cause may be wholly nervous, inasmuch as patients, in other diseases, as in typhus fever, without being in the slightest degree jaundiced, have seen every thing yellow. It is possible that different conditions may be occasionally concerned in the causation.]

The circumstances which *predispose* the system to an attack of jaundice are numerous. The melancholic or leucophlegmatic temperament, under mental excitement, whether of a pleasant or painful nature; an indolent mode of life, sedentary occupations, a full and stimulating diet,

and nabitual constipation, are among the most powerful.

The occasional or *exciting* causes of the disease are chiefly such as either suddenly stimulate the liver to an increased secretion of bile, or obstruct the free egress of that fluid. Thus, a heated almosphere, strong muscular exertions, sudden and powerful emotions of mind, spirituous or other fermented potations, a large and indigestible meal, fæces impacted in the transverse colon, pressure from a gravid uterus, may induce an attack of jaundice.

The *proximate* cause or essential nature of the disease evidently consists in an obstruction to the passage of bile in its course from the liver or gall-bladder to the duodenum, in consequence of which it either retrogrades into the blood-vessels of the liver, or is absorbed from the surfaces of the biliary ducts. There are many morbid conditions of the liver and its appendages, as well as of the adjacent organs, which may induce such an impediment. Not a few of these have been ascertained by the most conclusive evidence. Others, originally devised by the fertile imaginations of nosologists, and considered as adequate to the production of jaundice, have been successively handed down from author to author, not as merely probable causes, but as legitimate deductions from established facts. Instead, however, of specifying the greatest number of morbid conditions which may *possibly* give rise to jaundice, we shall endeavour to comprise, under a few leading divisions, those phenomena alone which pathology has clearly ascertained. Such, we think, may be conveniently arranged under four general heads.

1. Obstructions arising from biliary concretions or other altered conditions of the bile, as well as from worms, hydatids, or other foreign bodies.

2. Obstructions arising from diseased states of the liver, gall-bladder, or biliary ducts.

3. Obstructions arising from morbid conditions of the duodenum.

4. Obstructions produced by the pressure of enlarged contiguous viscera.

I. The first class of obstructions—**those arising from Biliary Concretions or other altered Conditions of the Bile itself**—have received an almost disproportionate share of attention from medical writers. The learned Heberden, for example, scarcely seemed to recognise any other causes of jaundice. There can be little doubt that a highly inspissated state of the bile may alone produce temporary jaundice. In some instances, after great depression of mind and torpor of bowels, the stools become white, and the skin of a dusky-yellow colour. Under the operation of a brisk mercurial purgative, the patient voids a quantity of dark, pitchy, viscid matter, of sufficient tenacity to be drawn out in threads. He becomes immediately relieved, the skin and the alvine dejections gradually resuming their natural colour Such cases we may warrantably refer to a thickened and vitiated state of the bile, which, in other instances, has been found of the same pitchy tenacious character while contained in the gall-bladder itself.

Biliary calculi unquestionably form a very frequent cause of jaundice. Their mere presence in the gall-bladder does not usually seem to produce either general or local inconvenience. Out of nineteen instances of biliary calculi, which occurred to Morgagni, besides four to Valsalva, in post-mortem examinations, not one had experienced jaundice. Yet a general failure of health has been observed, where, after death, no morbid appearance could be discovered except that of calculi in the gall-bladder. (Abercrombie on the Diseases of the Abdominal Viscera, p. 370.) Dr. Heberden remarks that, "in nearly twenty persons, a supposed pain of the stomach, which had frequently afflicted them for months or years, was at length joined by a jaundice." (Transactions of the College of Physicians, vol. vii. p. 171.) In those cases, it is probable that the occasional pain arose from some change in the position of the calculi in the gall-bladder. That they do not always remain in the bile-receptacle with impunity is clearly proved by the testimony of morbid anatomists. Soëmmering repeatedly found the mucous lining of the gall-bladder in a state of ulceration, occasioned by the irritation of the contained calculi; while other pathologists have observed a general thickening of its coats, and disorganization of its whole texture.

The *number* of calculi sometimes contained in the gall-bladder is almost incredible. Morgagni took out of one body 3646; and in the Hunterian museum at Glasgow, 1000 are preserved which are stated to have been extracted from one gall-bladder. The form and size of these calculi are very various. In a few instances they have nearly taken the shape and attained the magnitude of the gall-bladder itself, but generally, are from an eighth to a one-half of an inch in diameter, and of a polygonal form. (See Mr. Brayne's very interesting cases in the Medico-Chir. Trans. vol. xii.) The broken or divided portions of the larger calculi have sometimes corresponding convexities and concavities, proving that they were once united. And it is not improbable that the smaller calculi are often subdivisions of a larger mass, formed into distinct calculi before consolidation was completed. The sides of these calculi are often flattened as if from close contact and pressure.

The chemical and physical characters of biliary calculi have been already described in this work under the general title of Calculus. In that condensed but highly-interesting article the distinguished author has given a very perspicuous account of the more frequent forms of biliary calculi; but may not have thought it necessary to allude to one or two kinds of uncommon occurrence, which yet, we conceive, may prove of some importance in a pathological point of view. We, therefore, make no apology for introducing them in this place.

The first of these, as we are informed by Professor Turner, was discovered by M. Bizio, of Venice, in a peculiar fluid, quite different from bile, which was found in the gall-bladder of a person who had died of jaundice. It is of a green colour, transparent, tasteless, and of the odour of putrid fish. It is unctuous to the touch, may be scratched or cut with facility, and has a specific gravity of 1·57. M. Bizio has given it the name of *erythrogen*. (Dr. Turner's Elements of Chemistry, p. 656.)

Another remarkable kind of biliary concretion is described by Dr. Marcet, in the following words. "Within the last few days, I have seen and analyzed a large biliary calculus entirely different in its chemical composition from the above description, and, as far as I know, presenting a new fact in the history of these bodies. This concretion contained no adipocire (cholesterine), and consisted wholly of carbonate of lime tinged by bile. It was of a bright yellow colour. It was heavier than water, and measured two inches five-eighths in length, and two inches and a quarter in its largest circumference." (Marcet on Calculous Diseases, p. 151, note.) This extraordinary production was found in the gall-bladder of a dead body by Mr. Green, (now Professor Green,) demonstrator of anatomy in St. Thomas's Hospital.

The *formation* of biliary calculi is still involved in much obscurity. Many of the circumstances before enumerated as predisposing to jaundice generally, are found peculiarly to favour the formation of calculous concretion. Such are depressing emotions, deficient bodily exercise, a full diet and frequent constipation. Had biliary concretions been always found to consist merely of inspissated bile, there would have been no difficulty in conceiving how the want of exercise and similar causes, by favouring the retention of bile and the gradual absorption of its thinner parts, should ultimately lead to an actual concretion of the residual mass. And that this has sometimes occurred is sufficiently proved. Van Swieten, in his Commentaries, relates the case of a boy whose gall-bladder contained eight pounds of a thick sort of bile, consisting of a number of concentric strata, each stratum becoming firmer as it approached the circumference. There had, however, been no jaundice, although the stools were of a white colour. Biliary concretions, however, very rarely consist of bile alone; and even where an admixture of bile or a distinct stratum of bile does exist, the central portion is generally of a very different nature. Something more, therefore, than consolidation must take place. Either the original secretion of bile must be faulty, or, in consequence of long retention in the gall-bladder, it must undergo some changes by which its constituent parts become disunited or converted into new products. Probably these different states of bile occur in different cases; inasmuch as calculi are sometimes found in the liver itself, and inasmuch, too, as some kinds of calculi approach nearly to the known constituent principles of the bile, whereas others exhibit characters of a very dissimilar kind. May not also the mucous secretion of the gall-bladder become so altered in its nature, in consequence of the long retention of vitiated bile, as itself to furnish nuclei around which the dissociated constituents of the bile, or new formations from it, arrange themselves? The peculiar nature of some of the nuclei, as well as the effect of long-restrained secretions on other mucous surfaces, afford some countenance to this idea; although it must be admitted that the gall-bladder, from the adaptation of its structure to its peculiar function as a receptacle, is less likely to suffer from the detention of its contents than other mucous tissues exposed to the long-continued contact of their secretions.

An inquiry into the power by which biliary calculi are propelled forward necessarily involves some interesting points connected with the structure of the gall-bladder and the biliary ducts, which would lead us into a discussion somewhat foreign to the practical object of this paper. We shall merely remark that the effort of vomiting, whether spontaneous or otherwise, has probably a considerable influence in the extrusion of these concretions. Dr. Pemberton, indeed, does not ascribe any such effect to vomiting, unless where a calculus, from its peculiar size and form, entirely blocks up the duct, and obliges the bile to accumulate behind it, thus forming a kind of wedge which thrusts it further forward. To us, on the contrary, the impulse given in the act of vomiting would promise to be more effectual if the calculus did not very firmly or entirely close up the duct, but rather permitted the fluid bile, when strongly impelled, to slip along its sides; in which case, if the quantity of bile were too considerable to pass off quickly by the portion of the duct anterior to the calculus, it must necessarily swell it out, and thus prepare a way for the freer egress of the descending concretion.

We are not aware that any examples are recorded of very large calculi having passed through the biliary ducts; yet there is ample proof of the great distensibility of these passages. Dr. Baillie has seen both the ductus hepaticus and the ductus choledochus enlarged to the diameter of half an inch. When such a degree of distension takes place, there is generally a proportional thickening; in truth, an actual growth in every direction. Most commonly, however, if not always, when concretions much exceed the diameter just mentioned, they are expelled from the system by a different process; an adhesion is formed between the gall-bladder and the duodenum, and a sufficient opening effected by ulceration. The calculus thus brought into the duodenum is either then propelled along the intestinal tube and evacuated by the bowels, or a further adhesion takes place between the duodenum and the abdominal parietes; an abscess is formed; ulceration proceeds; and, at length, the irritating substance is protruded through the opening in the integuments.

The cases related by Mr. Brayne, to which we have before adverted, afford beautiful and striking illustrations of the former and more perfect mode of extrusion. The patients, in at least two instances, recovered. Of the *latter* mode of expulsion, to wit, that by an external opening, many examples are recorded, from which we may adduce one as related by the venerable Heberden. The patient, after having suffered for years from a discharging tumour near the umbilicus, was seized with acute pain, nausea, and vomiting, "et post paucos dies exiit calculus fellis tres pollices longus, totidemque ambitu, quique pendebat grana ccxlv." (Commentarii de Morborum Historiâ, &c. p. 213.)

Jaundice may be presumed to arise from biliary calculi, or other similarly acting obstructions, when its accession is sudden and accompanied by acute pain either in the epigastrium, or shooting towards that part from the back or right hypochondrium; especially if there be also vomiting and occasional shiverings, or profuse perspirations,

without any manifest fever or an increased force or frequency in the pulse. Not uncommonly, the pain precedes the appearance of jaundice, returning, perhaps, with great severity for several successive days, and remaining for several hours at each return. Unlike the rigors which forebode an attack of inflammation, the shiverings in jaundice rarely precede the pain, but occur irregularly during a paroxysm, and seem to mark a further propulsion of the calculus along the irritated canal, or its final extrusion through the distended opening of the common duct into the duodenum. The character of the pain is very important: it is acute, and occurs in paroxysms. Sometimes it is intense and excruciating in the highest degree, far exceeding what is felt in the most acute inflammation. The perspiration which sometimes drops from the patient may be ascribed chiefly to the severity of his suffering. The position of the patient also deserves attention. He bends the body forward upon his knees, when not writhing in other directions, and seems to find some relief from pressing upon the seat of pain. Not unfrequently the pain subsides on the appearance of jaundice. The state of the pulse will materially assist in the diagnosis. During the state of simple irritation it is seldom much accelerated or preternaturally firm. When, indeed, it becomes materially harder and quicker, the utmost vigilance should be exercised lest irritation should proceed to inflammation; in which case, the pain usually becomes more constant, the tongue whiter, and vomiting more incessant. These symptoms sometimes rise to such a degree as to resemble those of the ileus, to which, indeed, they then become nearly allied.

It may be proper here to intimate that the entire subsidence of the pain, vomiting, and other characteristic symptoms, does not necessarily imply the passage of the calculus into the duodenum. Very frequently it slips back again into the gall-bladder, there to remain for a time, with little comparative inconvenience to the patient. We need scarcely add, therefore, that the evacuations from the bowels should be carefully examined, inasmuch as the discovery of a calculus cannot fail to afford relief and comfort to the mind of the patient.

The *treatment* of calculous jaundice should be specially directed to three points:—

1. To facilitate the progress of the inhering concretion.

2. To mitigate the pain and other symptoms of irritation.

3. To guard against the inflammation which is to be apprehended from the irritation of the calculus.

In endeavouring to fulfil these indications, opium may be regarded as our sheet-anchor. The first dose, consisting of one or two grains, or an equivalent proportion of the sulphate or acetate of morphia, may be advantageously combined with five or six grains of calomel. If the pain and sickness do not abate, a grain of opium may be repeated at the end of the first hour, and reiterated, after similar or shorter intervals, until ease be procured. After a few doses have been given, a solution of some neutral salt, particularly the sulphate of magnesia, either with or without the carbonate, or the carbonate of magnesia with lemon-juice in an effervescing form, may be administered, in combination with some aromatic water, and repeated at fitting intervals, until a free evacuation from the bowels is obtained. Soda-water, well charged with carbonic acid gas, or simple saline draughts in a state of effervescence, are sometimes useful in allaying the urgent vomiting. If opium by the mouth should not procure ease, a drachm of the tincture may be mingled with a few ounces of thin starch or barley-water, and administered as an enema: prior to which, however, it is sometimes advisable to throw up a large quantity of warm water, which alone sometimes proves very soothing to the patient. As soon as possible, recourse should be had to a warm bath, in which the patient may remain until a degree of faintness supervene,—a state of relaxation peculiarly favourable to the passage of the calculus. Should these various methods be unavailing, and the patient be in a state to bear depletion, it will be expedient to withdraw from ten to sixteen ounces of blood from the arm, in a full stream, and, if practicable, while in the bath and in a half-erect posture. Topical bleeding may be also needful if the continued irritation of the calculus indicate inflammatory action, which may be apprehended from the pain becoming more constant, and accompanied with tenderness on pressure.

Emetics have been strongly recommended in calculous jaundice, and are doubtless powerful agents, though not always safe ones. When we consider the structure and the tortuous course of the common bile ducts, as well as the sharp and angular forms of the calculi, we shall not regard, without considerable apprehension, the action of a powerful emetic. In many instances inflammation, adhesion, and actual obliteration of the ducts, have resulted from the spontaneous passage of a calculus. Is it not, then, highly hazardous forcibly to impel these irritating substances against the already irritated mucous lining of the tubes?

Nauseating doses of ipecacuanha may, however, prove safer and more availing, if the patient be not already in a state of nausea. Such an exception is, however, very uncommon. The advantage to be expected from nauseating doses is of a twofold character. We may hope to promote more general relaxation, as well as to augment the biliary secretion; and thus, while relaxing the affected duct, and carrying down an increased flow of bile, nature may be assisted not a little in her efforts to expel the irritating substance.

We have already stated that the bowels are sometimes in a relaxed state. In other cases, however, they are obstinately constipated, and require strong and repeated doses of active purgatives, such as calomel, with the compound extract of colocynth, and an additional quantity of aloes. Even after the expulsion or retreat of the calculus, it will be desirable to exhibit occasionally a mercurial purgative, at the same time supporting the tone and regular action of the chylopoietic organs by small doses of a neutral salt in some mild bitter infusion.

We have mentioned hydatids, worms, and other extraneous matters, as occasionally producing jaundice. In some instances substances may be passed by stool which will enable the physician, in subsequent attacks, to form a reasonable conjecture respecting the nature of the obstruction. But,

generally, no such intimation can be obtained. The treatment, however, of jaundice from such causes must be very similar to that recommended for the removal of calculi.

II. **Jaundice arising from Diseased States of the Liver, Gall-bladder, or Biliary Ducts,** will of course be attended by the symptoms peculiar to each affection, in addition to those which characterize an obstructed state of the biliary passages. General or partial hypertrophy of the liver (a state not uncommon in great eaters); a tubercular or schirrhous condition of that organ; with many other forms of disorganization, may so interrupt the egress of the bile as to occasion jaundice. When the disease is dependent on such causes, there is sometimes no pain, or pain of a less acute, though more continued, character. The approach of the supervening jaundice is also generally gradual; and symptoms of hectic fever too often succeed. It is a remarkable circumstance that, notwithstanding the prevalence of liver complaints, calculi are rarely found in the interior of that organ. Morgagni affirms, "vix uno in jecinore mihi olim accidit ut invenirem; Valsalvæ autem in nullo, quod sciam." (Ep. xxxvii. Art. xi.)

Diseased conditions of the ducts themselves form, we believe, more common cases of jaundice than is generally supposed. Of these, inflammation and its consequences are among the principal. The mucous tissue of the ducts may become ulcerated, or so adherent as actually to obliterate the canal. It may, also, be so studded with tubercles as to be no longer permeable to the bile. Jaundice from such causes is often incurable and fatal.

III. Our third general division of jaundice comprises those **morbid states of the Duodenum, which have been found to occasion the disease.** Of such we may specify the following: 1. viscid mucus adhering to the inner membrane of the bowel, and sealing up the opening of the ductus communis choledochus. 2. a highly turgid or inflamed state of its mucous membrane. 3. a thickened, tuberculated, or otherwise disorganized condition of the duodenum.

1. Viscid mucus, we are persuaded, is a frequent cause of temporary jaundice. Many of the cases which have been gratuitously attributed to spasm, were probably of this nature.* If we attentively observe the peculiar structure of the termination of the common duct in the duodenum, we shall more accurately conceive how readily its small orifice, in the midst of a papillary projection, may be closed up by a thick and tenacious layer of mucus. Such a cause may be reasonably inferred when the disease has come on rather suddenly, has been unattended by acute pain or other inflammatory indication, yet has been preceded by dyspepsia and a torpid state of bowels. A mucous film upon the tongue, and the absence of the usual marks of chronic visceral disease, will give additional probability to the opinion. A large dose of calomel, followed by a draught containing magnesia and rhubarb in infusion of senna or some other vehicle, will sometimes quickly remove the disease. Much circumspection as to diet, the regular use of active exercise, with an occasional recourse to purgatives, may equally ensure a freedom from relapse.

2. A turgid or inflamed condition of the mucous membrane of the duodenum probably seldom exists without the lower portion of the common bile-duct being similarly affected. This form of disease is characterized by uneasiness or pain in the course of the bowel, which sometimes becomes tender on pressure, the uneasiness being more particularly felt at the expiration of three or four hours after eating, and being often accompanied with vomiting. The tongue has usually a white or yellow surface, and there is considerable thirst. The pulse is also somewhat accelerated. In distinguishing this affection from a diseased state of the pylorus, attention should be paid to the period after eating at which the vomiting occurs. Where the pylorus is alone affected, vomiting generally commences within two or three hours of the meal, and affords almost immediate relief. In the chronic inflammation of the duodenum, of which we are treating, the vomiting seldom occurs until four or five hours have elapsed, and does *not* alleviate the distressing sensations of the patient. He gains, however, sensible relief by taking a tea-cup full of warm fluid, which seems to excite an increased peristaltic action, and thus to liberate the oppressed duodenum from the undigested mass.

It is of extreme importance to overcome this kind of jaundice as soon as possible, lest disorganization of the duodenum, obliteration of the orifice of the bile-duct, or adhesion of its sides should ensue.

Whether simple turgescence or actual inflammation be the cause, the treatment should be essentially the same, varying only in degree. A moderate bleeding from the arm, if the strength of the patient admit of it; repeated local depletion; the warm bath; counter-irritants, particularly in the form of the antimonial ointment; with mild doses of saline aperients, and the most scrupulous attention to diet,—constitute the treatment which experience, no less than general principles, points out as best adapted for the purpose.

IV. **Jaundice produced by the pressure of enlarged contiguous viscera** is of frequent occurrence, although less susceptible of relief from medicine. Cases of simple distension of the transverse colon, from a collection of impacted fæces, are, of course, to be generally removed by appropriate remedies. Compression, too, by the gravid uterus, obviously admits of a natural cure. But a scirrhous enlargement of the pylorus, or of the round head of the pancreas,—two of the most frequent causes of this species of jaundice,—are among the most intractable as well as the most distressing disorganizations which human nature can sustain. In these cases, the most deplorable depression of mind, and an extreme degree of emaciation, are often observable. We have already alluded to some points of diagnosis in reference to the enlargement of the pylorus. As the disease advances, the tumefaction will be distinguishable by the hand: so may also, generally, though with more difficulty, the enlargement of the pancreas.

Affections of the head, irrespective of any previous disease in the biliary organs, have been sup-

* No special reference is made in this article to "spasmodic jaundice," because we have no evidence of its existence.

posed to occasion jaundice. Where, however, a serious injury has been inflicted on the head, such, for example, as is sometimes occasioned by a jump or a fall, it is highly probable that the liver or its appendages received some simultaneous injury, although the effect was not so quickly perceived. This is also the opinion of the judicious Abercrombie. We have, however, long felt assured that the state of the brain and nervous system has been too little considered in the pathology of jaundice. When we regard the influence of the brain and nerves in secretion generally, as well as their influence upon the moving powers, we may reasonably suppose that any considerable deviation from their sound and vigorous condition will be likely to lessen or deteriorate the biliary fluid; and also, by withholding a due supply of nervous energy from the moving forces, retard its transmission through the biliary passages into the duodenum. The remarkable influence which powerful emotions have upon the secretion of bile, and probably, also, on its propelling powers, should lead us more attentively to mark this connection, and the morbid changes thence resulting; by which attention, we may hope, at some future period, to clear up many obscure points relating to the biliary secretion, both in its healthy and diseased states, and ultimately arrive at more successful methods, not only of removing jaundice, but also, in many instances, of preventing its occurrence.

T. H. Burder.

[**Jaundice of the Infant, Icterus Infantum, Yellow Gown or Gum,** is a common affection of children everywhere. It comes on soon after birth, without any obvious cause, continues for some days, and disappears: the only other symptom generally observed being, perhaps, unusual drowsiness. It has been presumed to depend upon some irritation of the intestinal canal, resulting from the digestive system being called into active exertion for the first time, and receiving a new stimulus from the maternal milk. It is more probably owing to the ductus communis choledochus being obstructed by inspissated mucus, or by the meconium, which has collected in the intestines during utero-gestation. By some, it has been referred to too viscid a state of the bile; and by others to a congested condition of the liver. It is, however, an affection of no consequence. Even in torrid climates, recovery is so general, that opportunities have not occurred for discovering the precise pathological condition by dissection. It rarely exists at birth, but is commonly observed from the third to the seventh day—seldom in the second or third week; and terminates in death in the course of a week or two.

The disease would generally yield, probably, without any treatment; but inasmuch as the cause would seem to be, in many instances at least, obstruction of the choledoch duct, it may be well to facilitate its removal by gentle laxatives, as the syrupus rhei, magnesia, or castor oil. The writer has never found it necessary to adopt any other plan of treatment in the cases that have presented themselves to his notice; but should there be signs of hepatic inflammation, a few leeches, followed by an emollient cataplasm, and the warm bath, may be employed. In the more chronic form, remedies have been prescribed by some, the precise object of which is not very intelligible; and hence their action has been uncertain, if not null. (Condie, *A Practical Treatise on the Diseases of Children*, p. 520, Philad: 1844.)

Robley Dunglison.]

KIDNEYS, DISEASES OF. Notwithstanding the activity with which the kidneys perform their functions, the constancy of their action, and the extraordinary rapidity with which their secretion becomes affected, not only when other parts of the system are suffering under actual disease, but even when they are simply and slightly disordered, these organs are not peculiarly liable to alteration of structure. On the contrary, as it has been well observed by a distinguished pathologist of the present day, "in the greater number of diseases, whether chronic or acute, we cannot discover by dissection any change in the structure of the kidneys."

Of the diseases incidental to the kidneys, the most important, perhaps, are **ischuria renalis, nephralgia,** and **nephritis.** To these might be added **diabetes,** were pathologists agreed as to its primary seat; but though several eminent writers have considered it to originate in the kidneys, there are others of equal name and authority who have referred it to a different source. Ischuria renalis has been discussed in a former article; and it is proposed, likewise, to treat, under their respective titles, both nephralgia and nephritis.

In the present article, it will be our object briefly to notice those other renal affections which, on account of the rareness of their occurrence, or the obscurity and uncertainty of their symptoms, or their hitherto uncontrollable nature, may probably be deemed of minor importance so far as practice is concerned; yet which, by those who are truly devoted to medicine as a science, can never be deemed insignificant or uninteresting. The renal affections which we are about to consider may conveniently be arranged, after the plan adopted by M. Andral, under three heads: the first comprising morbid conditions of the circulation of the kidneys; the second, lesions of nutrition; the third, morbid formations.

1. **Lesions of Circulation.**—The kidneys are sometimes found gorged with blood—in that state to which the term **hyperæmia** has been appropriated without any other alteration. One or both organs may be thus congested, and the congestion may affect both the cortical and tubular parts, or only one of them. When they are in a high state of hyperæmia, they assume a dark chocolate hue.

The kidneys are also found in a state precisely opposite to that just mentioned, namely, in a state of paleness or **anæmia,** either partial or general, either complete or incomplete; sometimes existing in a few scattered points only. This is the condition of the kidneys which is frequently observed in persons who have sunk under chronic diseases, especially in dropsical patients, and those who have been the subjects of the affection named by Dr. Good **marasmus anæmia.** When this paleness exists in an exquisite degree, it may be regarded as in itself a disease, but hitherto it has

not been discovered to occasion any functional derangement during life.

The yellow colour, either general or partial, which is occasionally observed in the kidneys, is probably owing, as M. Andral has remarked, to a less advanced stage of anæmia.

It may suffice thus briefly to have noticed that congestion of the kidneys, or extreme paleness of them, may occur without their presenting any other morbid appearance. Such instances, however, are rare; hyperæmia, as well as anæmia, is usually found in connection with other degenerations of those organs: the former, for example, conjoined with softening, or with induration together with hypertrophy; the latter with softening, or occasionally with induration and atrophy.

2. **Lesions of Nutrition.**—The kidneys are sometimes much larger than natural, though otherwise unaltered. Both kidneys may be thus affected, but more commonly the **hypertrophy** is confined to one only. As was observed while treating of ischuria renalis, great augmentation of volume of one kidney is not unfrequently met with when the other is, by disease or obstruction, rendered incapable of performing its office. The enlarged gland takes upon itself the duty of its fellow. Hypertrophy of the kidney seems occasionally to depend upon its being doubly nourished, by receiving its supply of blood from two renal arteries. This state of kidneys, generally combined with increased vascularity, is the most usual morbid appearance observed in cases of diabetes. An extreme paleness of their tissue, with softening, has indeed been often mentioned as the principal alteration which takes place in them in that disease; but in various cases upon record, and in every instance which has occurred in our own experience, the kidneys have been more vascular, and generally larger than natural.

To this variety of morbid alteration—hypertrophy—may, perhaps, be referred those cases where the kidneys are united by an intermediate substance; a sort of middle lobe, resembling them in its texture, and passing over the vertebral column from the one to the other.

With respect to the nature of those hard, whitish, globular bodies, of various sizes, which are mentioned by authors as existing in the cortical substance of the kidneys, and which in some few instances have been detected in the tubular substance also, little is known. Some have regarded them as serving to secrete the urine, while others have supposed them to consist of a mass of vessels interlaced: but it is clear that granulations like these sometimes constitute a really morbid state. They nearly resemble the yellow granulations of the liver, which Laennec thought an accidental tissue, and to which he gave the name of *cirrhosis;* but which, in all probability, are the result of an unusual development of one of its elementary tissues, namely, of its white substance. These granulations in the kidneys are sometimes thinly scattered, sometimes so very numerous as to leave hardly any trace of their cortical portion, and even to occupy the intervals between the cones of the tubular portion of them. Such a state of the kidneys may, it would seem, produce dropsy; for in various cases of dropsical patients no other morbid appearance of importance has been detected. Although, as M. Andral observes, it is difficult to comprehend how dropsy is produced by this affection, the fact is nevertheless certain.

[Under the head of Dropsy, (vol. i. p. 707,) attention has been drawn to the *Granular Disease of the Kidney, Morbus Brightii*, which is attended with the secretion of albuminous urine — hence termed *Albuminuria*. Yet the appearance of albumen in the urine is by no means diagnostic of this condition of the kidneys, as has been shown by the observations of the writer, and of others, (*Practice of Medicine*, 2d edit. ii. 29, Philad. 1844); and cases have been published recently, in which, on the one hand, Bright's disease existed without albuminous urine; and on the other hand, albuminous urine was present without Bright's disease. We cannot, indeed, with certainty, infer the existence of any particular organic disease of the kidney from the existence of albuminous urine.

By those who look upon all morbid derangements to be the result of inflammation, granular disease of the kidney has been thus regarded, and hence the term *nephritis albuminosa*, which has been given to it. Like other morbid degenerations, however, it is owing to a *vice* of the system of nutrition, which is inexplicable. (Christison on *Granular Degeneration of the Kidneys*, Edinb. and Philad. 1839; or an abstract of the same in Tweedie's *Library of Medicine*, 2d Amer. edit. iii. 271, Philad. 1842; also, Rayer's *Traité des Maladies des Reins*, 2e livr. Paris, 1837; Martin Solon, *De l'Albuminurie*, &c., Paris, 1838, and A. Dalmas, *Dict. de Méd.* xxvii. 364, Paris, 1843.)]

The kidneys, again, are subject to general or partial *atrophy*. In the former case, one or both of them may be diminished in size, without being altered in structure, and without any symptoms of disorder of the urinary apparatus having been present during life. Such a condition of kidney may have been coeval with the patient's birth; or the atrophy may have been the result of mechanical compression; of a tumour in the vicinity of the gland; or of a collection of pus formed around it. One kidney may be wholly wanting; and this defect may be either congenital, or the consequence of disease. Of the former occurrence, a remarkable example has been given by Morgagni, Letter 31, Art. 25. In the patient there referred to, there was no trace of the left kidney, but the deficiency was supplied by the right, which was double the natural size, and furnished with a double pelvis and ureter; and both ureters went to the right side of the bladder. When one kidney has been destroyed by disease, no inconvenience may arise, provided the remaining one be sound; but if that be also degenerated, it is obvious that the patient will experience much and severe suffering. An instance is given by M. Andral, where dropsy, of which the organic cause could not be discovered during life, was ascertained to have arisen from great disease of the urinary apparatus; the left kidney was totally gone; the right was enlarged, softened, and studded with those whitish granulations which have been already noticed.

Several curious varieties in the form and the situation of the kidneys are occasionally met

with; but they can scarcely be considered as diseases, or, if they be so considered, they are not to be recognised by any peculiar symptoms, nor can they ever be influenced by medical treatment.

The morbid states we are next to mention, are *softening* and *induration*. The former state is not unfrequently conjoined with turgescence or hyperæmia, and this combination may be regarded as affording strong evidence of inflammation. In patients who, during life, have suffered under symptoms of nephritis, a very soft state of the kidneys, with intense redness, has been observed. The same condition has also been found accompanying certain chronic affections of the bladder, as thickening of its inner membrane.

There is a peculiar softening of the kidneys, which has been described by Dr. Baillie, and by Mr. Wilson, in his lectures. The kidneys are converted into a soft loose mass, resembling in appearance common sponge. When shaken in water, the parts all separate from each other, somewhat like the unravelling of the shaggy vessels of the placenta. In one such case, small shreds, apparently portions of blood-vessels, had been passed by the urethra; and upon examination after death, Mr. Wilson conceived that they might have come from the kidneys during life. This is one of those lamentable states of disease over which, even if known to exist, our art can exercise no power.

There is another kind of softening, in which the substance of the kidneys is extremely pale, or of a grey tint. This alteration has been found where no symptoms of the disease of the urinary organs had manifested themselves.

Induration of the kidneys may be attended by congestion or by paleness of their tissue. In the former variety, the organs are generally enlarged; in the latter, they are also occasionally enlarged, but most commonly diminished in size. In the pale induration, the kidneys, though firmer than ordinary, may yet retain their natural structure; or they may be almost as hard and as white as cartilage, their natural structure being entirely lost. This is the state which has been called scirrhus of the kidney. It is very rarely met with, and the symptoms attending it are not to be distinguished from those which belong to other renal affections. When both kidneys are thus diseased, very little urine will be secreted, or there may be complete ischuria renalis. The remedies we must employ, must of course be those which have been useful in nephralgia and in suppression of urine. Opium and hyoscyamus are more likely to afford relief than any other medicines.

3. **Morbid Formations.** — Of the diseases belonging to this division of our subject, the most important is that very formidable and intractable malady first accurately described by Mr. J. Burns, under the title of spongoid inflammation; but more generally known by the appellation of *fungus hæmatodes*, assigned to it by Mr. Hey. Until of late years, it was commonly confounded with cancer, of which, indeed, it is still reputed a species by some writers of high reputation. In this light it is regarded by M. Roux. Mr. Wardrop has named it soft cancer; and Mr. Langstaff has remarked that sometimes the scirrhous, medullary, and fungoid structures, are so blended in various parts of the same subject, that they appear like different stages of morbid growth, and the difficulty the pathologist experiences is in deciding whether the disease is of the cancerous or hæmodotal kind, or *whether they are not of the same class*. The same author refers to Sir Everard Home, as stating that the fungoid and the cancerous sore are the effects of one disease, only varying according to the structure of the parts which it attacks. As, however, it is now ascertained that the same structure, the female breast for example, is liable to either disease, and that fungus hæmatodes has been observed in almost every part of the body, the position of the last-mentioned pathologist is no longer tenable. It may be admitted that, in the malignancy of their character, as well as in some other points, fungus hæmatodes and cancer bear a strong resemblance to each other; but at the same time we must maintain that the former disease wants the pathognomonic signs by which cancers are distinguished. (See Fungus Hæmatodes.)

Mr. Wardrop first noticed fungus hæmatodes as affecting the kidney; but he acknowledges that, in the case he relates, the morbid alterations of structure would not have been alone sufficient to warrant him in calling it fungus hæmatodes. He conjectured it to be such, because there was fungus hæmatodes over the hip-joint. Since the publication of his work, however, several well-marked cases have been given in detail by M. Langstaff. In one of these, the subject of which was a man aged seventy, affected by hemiplegia for several years, the symptoms were, for a length of time, difficulty of voiding the urine, which was usually tinged with blood, and afterwards retention; great pain in the region of the left kidney, and uneasiness of the rectum. He died apoplectic.

In another very interesting case, that of a young lady, the symptoms were frequent desire to relieve the bladder, and in the course of a few hours an immense quantity of limpid urine was discharged, without alleviation of the urgent propensity to void more; then, the irritability of the bladder increasing, arterial-looking blood was discharged in considerable quantity. Some doubt existed at first as to the source of this hemorrhage; there was some reason for suspecting it might proceed from the uterus, but the introduction of the catheter at once settled the question. After several recurrences of hemorrhage, accompanied by great irritability of stomach and bilious vomitings, the discharge of blood ceased for a time, but then the urine was very turbid, and deposited a mucopurulent sediment. About six weeks subsequent to the first attack, dull pain was complained of in the right side, and upon examination a tumour was distinctly felt in the right hypochondrium, and traced into the iliac region: there was pain upon pressure, and pulsation of the part. The discharge of blood afterwards returned at intervals, and the tumour increased greatly, in despite of all the means that could be devised for checking its growth. The patient's general health of course suffered dreadfully, and sometimes she appeared to be reduced to the last degree; yet, in the intervals of the attacks of pain, sickness, and hemorrhage, she rallied in a surprising manner; nor was it until five years and a half from the com-

mencement of her sufferings that she sank under them. Upon examination after death, it was found that the right kidney occupied the principal part of the abdominal cavity: the diseased mass, with a portion of the liver, which adhered to it, weighed eleven pounds and thirteen ounces. It was almost entirely formed into protuberances of different sizes, and the peritoneal surface was greatly condensed. When that part of the tumour which constituted its chief bulk was cut into, it was found to contain a coagulum of blood, not adhering to the sac, and weighing three pounds, and composed of concentric layers, as in an aneurism which has formed rapidly.

The left kidney, which weighed twelve ounces, was much altered in structure, being chiefly occupied by pulpy tubera, which were rendered red by minute injection.

In the Medical Gazette for May, 1831, is related a case of fungus hæmatodes of the kidney, in a subject only four years of age. In this instance, the symptoms of renal affection were so trifling, that no suspicion existed in the mind of the medical attendant that such affection was the sole, or even the chief cause of the little patient's distress. It had been conjectured, as in Mr. Langstaff's case just mentioned, that the liver was enlarged; but the apparent hypertrophy of that viscus was occasioned by the enlarged kidney, which pushed it upwards and outwards towards the diaphragm. These unhappy cases have hitherto resisted every mode of treatment. When fungus hæmatodes attacks external parts, it is still one of the opprobria medicinæ; what, therefore, can be expected from our art, when its ravages are obscurely going on in internal organs?

The formation of *hydatids* has been stated as being no uncommon disease of the kidney. It would, however, seem that the true hydatid is not often met with in that situation; while those cysts with thin and nearly transparent parietes, and which contain a limpid colourless fluid, very like water, but having some coagulable matter, are of frequent occurrence. These may be dispersed over the surface of the kidney, or be imbedded in any part of its substance. They often attain an enormous size, so as to occupy by much the larger portion of the gland; and they vary in number, from a single one to many hundreds. Each is a distinct bag, and does not contain others within it. It is probable that these cysts depend upon a morbid alteration of the structure of the kidney.

In the true hydatid the cyst is thicker and much firmer: and, when cut into, appears laminated. Within the bag there is sometimes only one hydatid, but generally there are a considerable number; some attached to its parietes, others loose and floating in the fluid. These hydatids sometimes have numerous others adhering to their inner surface, or floating freely in their cavity. (See Hydatids.)

We possess no other distinct evidence of the presence of hydatids than that which their being passed by the urethra with the urine affords. All the other symptoms, such as pain of back, symptomatic fever, nausea and vomiting, belong equally to other renal diseases. Every modification of treatment has been tried, when their existence has been positively known, or has been suspected, but in vain. An artificial outlet cannot be made for them. When they obstruct the flow of urine, as sometimes happens, the bougie or catheter must be employed. Under the steady exhibition of turpentine the pain of the loins has been known to cease, as well as the passing of hydatids; but in many instances the same remedy has totally failed. The muriated tincture of iron has been given, but with no permanent good effect.

Of the remaining morbid formations in the kidneys, *tubercle* is the only one which merits the least attention. It is very rarely found in them, and, when it is, generally exists in other organs also. The tubercle of the kidney is said by Dr. Baillie to resemble exactly the common tubercle of the lungs.

Fatty matter and *gelatiniform matter* are now and then observed in the kidneys, and they have been found converted into a bony or earthy substance. But these morbid appearances are of extreme rarity.

We have thus endeavoured to furnish a sketch of those diseases of the kidneys which, though hitherto little understood, could not, in a work like the present, be passed over with propriety. In the actual state of our knowledge, our descriptions must necessarily be imperfect. The period may be distant in which their nature and symptoms will be thoroughly comprehended. The most patient attention to the phenomena of certain diseases, the most diligent search into the morbid changes produced in the structure of parts by morbid actions, may for a long time seem to be unproductive of any important practical results; still, patient investigation should never be abandoned. It may be the good fortune of others hereafter to elucidate what is obscure in the affections of which we have just given a brief account; it was our duty to record what is already known respecting them.

H. W. Carter.

LACTATION.—Lactation in the human female, when naturally conducted, cannot be called a disease; but even under the most favourable aspect there are often circumstances which require attention and regulation, both for the purpose of alleviating pain and of preventing mischief. There are, moreover, so frequently interruptions to this usually healthy process, and there are so many important questions connected with the flow of milk at various periods, that it becomes necessary, in a work on practical medicine, to discuss them, although somewhat briefly.

The close sympathy between the uterus and the mammæ is evident even in the unimpregnated condition. At puberty the breasts enlarge and their glandular structure is developed; a day or two before menstruation, and during the period itself, the breasts become tumid and more or less painful. There is an affection which may be termed *spurious pregnancy*, described by Dr. Gooch, where, apparently from uterine irritation, the breasts are swollen and affected with shooting pains, and even a serous fluid resembling thin milk oozes from the nipple, being precisely what takes place in real pregnancy, wanting only the darkened areola. In some diseases of the uterus, particularly in hypertrophy of that organ, a similar state of the breasts is often observed. In real pregnancy the altera-

tion in the breasts is strongly marked, and the quantity of milky serum which is secreted is sometimes very copious, especially towards the close of utero-gestation. Sauvages mentions an instance where as much as a pint and a half was daily poured out as early as the fifth month. Many women, however, show no appearance of milk at all before delivery, who yet have abundance afterwards. After parturition it is usual to place the child to the breast within the first twenty-four hours, partly to draw out and form the nipple before any hardness of the breast occurs to render that difficult, and partly to encourage the flow of milk,—for at a later period the contact of the child's mouth will immediately excite it. With first children there is rarely any quantity secreted before the third day; about that period, but often a day or two later, the breasts become hard and swollen, hot and painful; the pulse is quickened, the skin above the natural temperature, the thirst urgent, the sleep broken and troubled with unpleasant dreams, and the sensorium disturbed, so that the patient, whilst yet awake, will fancy strange objects about the bed. The process goes on, more or less rapidly, till the milk is at the height, as it is termed, when the breasts are extremely hard, and the gland is felt knotted and loaded, and is at the same time very tender; the swelling may extend quite to the clavicles and under the arms, the axillary glands being similarly affected; a small quantity of milk will often ooze out from the nipples, particularly if the breasts be fomented, or gently pressed with the hand. If the child be put to the breast, the action of suckling is attended with great pain to the mother, but followed by much relief. As the milk flows, the hardness diminishes, and the swelling subsides. After a few hours, if the milk be freely and frequently drawn off, the sensations become more comfortable, the pain is removed, the breasts are only distended when the child has been long away, the pulse and skin are restored to their natural state, and the process of lactation is then fairly established.

In the management, up to this period, much may be done for the relief of the patient. As soon as the symptoms begin, a purgative may be administered with great advantage, and one which contains the neutral salts in combination, as it will promote watery discharges from the bowels, is preferable: this should be repeated in twenty-four hours, or earlier, if the case is severe. There is distressing thirst, but if we allow a too free indulgence in liquids, the distension of the breasts is increased; it is therefore better to allow only a small quantity of drink at a time, and perhaps nothing is so effectual in a small bulk as an effervescing saline draught frequently repeated. As a new-born infant will often experience much difficulty in drawing out the nipple of a hard and swollen breast, or in extracting the thick milk itself, it is often advisable to have this done by an older child or a grown person, or by artificial means. These consist of various sorts of breast-pumps, where a smooth-edged glass tube is placed over the nipple, and a vacuum being produced by suction or by syringes, or by heat, the milk is thus drawn off, and the buried nipple made to project. Great benefit may be obtained by fomenting the hardened breasts with hot water, or by applying mild poultices, which promote the easy flow of the milk and relieve the distension. This is also often effected by small wooden bowls soaked in boiling water, and wrapped up in flannel, which are then placed over each breast. As a more permanent application, hare-skins are often used; cabbage-leaves were also formerly much in vogue to promote a copious perspiration over the surface; the smell, however, is very unpleasant, and the same advantage may be gained by oiled silk.

The milk first drawn has a purgative quality, and thus serves to carry off the meconium which is loading the large intestines. On this account, when a child does not get the first draught of the breast, from being nursed by a wet-nurse, or from being brought up by hand, a gentle purgative should always be given; diarrhœa of an irritable character, and even convulsions, often being produced from retained meconium. In this country it is usual to give a purgative under all circumstances, but it is not customary in many parts of the continent, and it is doubtful whether it be not often superfluous. By the experiments of Dr. Robert Lee, it would appear that the meconium is an excrement, and does not contribute to nourishment; but that above the situation of the meconium a quantity of highly nutritious albumen is found in the intestines, serving for the sustenance of the infant till lactation is established. A purgative given before that period will therefore carry off this substance, and artificial nourishment must be given to make up for the loss of the natural provision.

The milk varies considerably in condition during lactation. At first it is thick, yellowish, and having a very large proportion of cream; several days elapse before it possesses its natural appearance, which should be thin, bluish, and sweet. The quantity of cream varies very much according to the diet, and the frequency with which the breasts are drawn. Some milk has a decidedly saline taste; and at other times it has been distinctly bitter, so that the child will turn away from the breast in disgust. Its taste and qualities may be easily affected by articles of diet, by passions of the mind, repletion, hot rooms, &c. and the child is more or less disordered by the alteration. Medicines will often affect the milk in a very striking manner; a purgative given to the nurse will frequently act violently upon the child, without in the least affecting the individual herself; in the same way, alkalies given to the nurse will relieve acidity in the child's stomach; and mercury given through a similar medium will cure syphilitic symptoms in the infant at the breast.*

Milk has been said to be sometimes black or green, but there is in such cases most probably a mixture of blood, from the exterior or interior of the nipple. The writer has seen four instances where it was of a golden yellow colour, and where, upon standing, a thick layer of bitter cream, as

* On the authority of Mr. Keate, it may be here stated that a foreign gentleman, a patient of his, was in the habit of regulating his hepatic system, when there was a deficiency of bile in his motions, by taking asses' milk medicated by giving the animal a certain quantity of a mercurial preparation (the nitrate of mercury). The effect was very marked, and he could bear mercury in no other shape.

yellow as puro bile, floated on the surface. In neither of these cases was the patient jaundiced; but a very copious flow of bile being kept up from the intestines by mercurial purgatives, after a few days the yellowness gradually disappeared; the child, till then, having been much griped and affected with diarrhœa. In no cases where wet-nurses have been jaundiced, has the writer seen the milk yellow; and it is no uncommon thing for them to become thus disordered, upon a sudden transition from poverty and a scanty diet to a full and luxurious mode of living. Milk will disorder an infant from merely being too rich, without its being otherwise altered in character. The remedy here will consist in purging the nurse, making her take plenty of active exercise, and putting her upon a more spare diet. The properties of the milk will also be considerably influenced by pregnancy or by menstruation.

There are some popular errors upon this point, which it is not difficult to expose. One is, that women will not become pregnant during lactation. This is far from being the case, and Mr. Roberton of Manchester (vide Edinb. Med. and Surg. Journal, No. 110) has taken the trouble to inquire minutely into the result of 160 cases, in which he found that eighty-one women had become impregnated during suckling. Mr. Roberton has stated "that the appearance of the catamenia during lactation does not appear to have any influence in disposing to conception." In this respect the writer's experience leads him to a different conclusion: he is decidedly of opinion that those women who menstruate during pregnancy will more readily conceive than those who do not; and he has also remarked, as Dr. Hamilton has done, that both these occurrences are more common with first children; hence women under such circumstances are not, *cæteris paribus*, so eligible for wet-nurses. Dr. Mason Good has recommended cohabitation with the husband during lactation, as likely to increase the quantity of milk; arguing upon the fact that the Tartars are accustomed to irritate the vagina of their mares for a similar purpose. The objection to his proposal will only apply to hired wet-nurses, lest they should become pregnant. Wet-nurses have very frequently recommended themselves to the writer on the plea that they have still continued to menstruate, by which they believe that their milk is *renewed*, as they term it, every month, so as to be rendered fit for much younger children than it would otherwise have been. This occurrence, however, much impairs the milk, in its probable duration, and in its properties at the period itself. The infant becomes unusually fretful, brings up the milk by vomiting, and has frequent watery motions of a spinach-green colour. These symptoms are so peculiar, when arising from no very obvious cause, that it may be generally safely guessed that the nurse is either menstruating at that moment, or will do so on that day month; for it is not uncommon to find the effects on the child brought on, although the alteration in the uterine condition of the nurse is not complete.

One of the most early and most troublesome attendants upon suckling is *soreness of the nipples*, as the pain recurs as often as the infant is put to the breast. Very few escape some degree of tenderness, with first children especially, but the inconvenience is soon obviated, and the delicate skin becomes callous, like the fingers of a harp-player —an effect which may be hastened by some slightly astringent or gently stimulating lotion, as green tea, brandy, weak solutions of the sulphate of zinc or of alum. If more severe and intractable, a solution of one to two grains of nitrate of silver in one ounce of rose-water will be found of service. Should the skin become excoriated, or should a crack take place at the junction of the nipple to the areola, a shield of glass, wood, ivory, or silver, should be used, with an artificial or prepared cow's teat, through which the child may suck without biting or much disturbing the nipple. The surface of the sore may then be freely touched once a day or oftener with the lunar caustic, and in the intervals the part may be kept well smeared with ointment containing honey, or a minute quantity of Peruvian balsam. Preparations containing lead or mercury in any form are scarcely advisable, as they may be swallowed by the infant. Where the surface of the nipple is not chapped, but unusually hot and dry, and very tender to the touch, all astringent lotions and stimulating applications aggravate the mischief; the simplest ointments, of wax and oil alone, will be found to agree best, or the part may be covered with powdered gum arabic or a bread-and-water poultice. The dress should, in all cases, be carefully kept from irritating the sore nipple, by means of wax cups, shells, or glasses for the purpose.

There is one species of sore nipple not often noticed by practitioners, (who are too apt to leave these cases to the management of the nurses,) which the writer has found more intractable than any others, and the means frequently of inducing the mother to give up suckling entirely, from the constant torture to which she is exposed. There is little or nothing to be seen but a small spot at the orifice of the nipple, which is elevated and irregular in appearance, extremely painful to the touch, and exuding a sanious ichor. When the child is put to the breast, the pain is most acute, and seems to come from the interior of the nipple and breast; and the first and last milk is generally mixed with blood. It would appear as if the interior or lining membrane of the lactiferous tubes was in a morbid condition. Little or nothing can be done for this affection. The free application of caustic to the external orifice, and poulticing the breast, has now and then effected a cure, along with careful attention to the stomach, bowels, and general health, which is highly essential. Those who have uniformly suffered from sore nipples on former occasions have frequently seemed to prevent them by using, previously to parturition, for several weeks, either an astringent or demulcent lotion, according to the state of the skin.

Inflammation will occasionally attack the breast itself at any time during lactation, but most frequently at a very early period, when there has been exposure to cold, much trouble in the first management of the milk, or soreness of the nipples; it does not so frequently happen where the milk is at once driven back without suckling the child. If not immediately treated by leeches, by fomentations, and poultices, hot and frequently changed, or, as some prefer, by cold lotions, abscess

will take place, accompanied by great pain and much constitutional disturbance. The treatment of this state comes within the immediate province of the surgeon; but there are one or two circumstances respecting *milk abscess* deserving of notice in this place. It is very customary when abscess is threatened, to persevere in keeping the child to the breast, or otherwise drawing the milk off; partly to enable the patient to continue suckling, and partly to prevent the milk collecting in and distending the inflamed breast. If the inflamed portion be not extensive, there is no objection to this, as a small abscess will not much interfere with the functions of the remaining sound parts; but if the whole, or nearly the whole, of the breast be implicated, the pain of suckling will be very violent indeed, and the frequent disturbance and irritation will contribute to increase the inflammation, and diminish or entirely obviate the chances of preventing the formation of matter. Should abscess be formed, and matter be felt fluctuating, the most experienced practitioners agree upon the propriety of puncturing early and freely; otherwise in such a peculiar structure most extensive mischief will take place, and the surface remain disfigured afterwards in the most unsightly manner. It is curious to notice in subsequent confinements how little the real glandular apparatus has been destroyed, even where large collections of pus have formerly been evacuated, so that the patient will sometimes be enabled to nurse with but little trouble; although from some partial obliteration of the ducts, there is always rather more difficulty in the flow of the milk.

Milk Fever.—What is called *milk fever*, is an aggravated and morbid form of the healthy and natural excitement which takes place at the onset of lactation. The febrile symptoms are much more severe; there is a well-marked precursory rigor; there is great pain and throbbing of the head; a flushed countenance; intolerance of light and sound; the pulse is full, hard, and rapid; the thirst excessive; the skin hot and dry, and the tongue covered with a thick fur. These attacks may be usually traced to a too stimulating diet, a heated atmosphere, much exertion and disturbance, or mental agitation. They are much less frequent than formerly, when great fires, loads of blankets, and brandy caudle were the usual appendages to a lying-in chamber. If the flow of milk be encouraged, and gently yet freely drawn off; if the room be kept cool; agitation soothed or avoided; purgatives duly administered, and perhaps diaphoretic medicines; a remission of the symptoms will usually take place in a few hours, accompanied by a copious perspiration and tranquillity of pulse. On the contrary, by bad management phrenitis may supervene, of a very dangerous character; when the milk will be entirely suppressed, and nothing but the free use of the lancet will save the patient.

A very common expression is, that in such cases *the milk flies to the head*. In phlegmasia dolens the milk was also supposed to fly to the leg, and hence the French writers formerly called it, "dépôt du lait." It has several times happened in the writer's experience, that where bleeding has been had recourse to in inflammatory diseases with sudden suppression of milk, the serum of the blood, when separated by rest, has been white, opaque, and bearing nearly all the characters of milk, except the formation of cream on the surface. It may here be observed, also, that where the milk is driven back artificially, and active purgatives are employed, a great quantity of milk-like fluid may be generally seen in the motions. Depressing passions, fear, and anxiety, will suddenly drive off every vestige of milk; but the only genuine *translation* may be said to be those extraordinary instances where the milk has receded more or less rapidly from the breast, and a vicarious discharge has taken place from other parts, the general health remaining but little affected. The most common example of this is where the discharge has taken place from the vagina in the form of leucorrhœa; but it has also occurred from the fauces, the navel, the eyes, the kidneys, the whole surface of the mammæ, &c.

Where the child is to be weaned, or where a mother does not wish to suckle, or is not able from constitutional debility, or local defect, or where the death of the child has taken place, it becomes necessary to "*backen*" the milk, as it is vulgarly termed. This may be done the most safely for the mother by her not being too impatient. If cold evaporating lotions are applied to the breasts, there is a more rapid dispersion of the milk, but there is more risk of fever, phrenitis, &c. It so happens, however, that these cold lotions rarely are allowed to act as such, for nurses in general are so particularly careful to cover up the patient's neck with the bedclothes and wrappers, that the lotions very rapidly become warm fomentations. In the writer's opinion, the best and safest applications consist of stimulating liniments, applied warm and also constantly, by means of layers of lint or flannel. The breasts should also occasionally be gently pressed and rubbed with warm oil; and if they are very hard and distended, a small quantity may be now and then squeezed out or drawn off artificially. The bowels are to be actively kept open by saline purgatives; the diet is to be low, and the quantity of drink lessened. It will be but a few hours before the extreme distress is mitigated, but it will be often several days before the milk is thoroughly dispersed, or the remedies can be discontinued. The sensation of "draught of milk" in the breasts will sometimes be felt two or three times a-day for weeks afterwards. In weaning a child, however, it is often the plan to do it so gradually, by accustoming it to partial feeding for some time previously, that little trouble is at last experienced in dispersing the milk. It is still very desirable that opening medicine should be plentifully given, even under such circumstances; as from this discipline being neglected, patients will often suffer for months afterwards, with great depression of spirits, loss of appetite, feeling of weight and lassitude, and general ill health,—sensations which are soon relieved by having recourse to opening medicine.

An excessive secretion of milk will sometimes be met with; but in nearly all these cases there is apparently some defect in the organization of the nipple, or the lactiferous tubes have lost their elastic property of retention, for in the intervals of suckling a constant and very copious discharge of the milk takes place. The daily waste and drain cannot exist long without materially affecting

the health and strength ; and unless the flow can be kept in check, there is no remedy except weaning the child, and repelling the milk altogether. Various plans have been proposed, but the trial is not often successful. Local strong astringent applications, as lotions of alum, oak-bark, zinc, &c., sometimes do good, but they are apt to effect too much, and drive away the secretion entirely. The astringent tonics internally, particularly the mineral acids, steel, kino, and alum, have occasionally been of service. Belladonna has been advised, both locally and in small doses internally. The breasts should be kept as cool as possible, and cold bathing be daily had recourse to.

The period of lactation is generally one of the most healthy of a woman's life; but there are many exceptions to this; and many who have begun with success, by continuing to suckle too long, by a too limited diet, by much loss of rest, or by other causes, have had their own health and that of their infants considerably and even fatally impaired. A recent writer has attempted to define the exact period to which suckling should be limited, as far as the advantage of the infant is concerned ; but all such definitions are constantly contradicted by experience. There is much fallacy also in the arguments to prove that protracted lactation is the cause of various infantile diseases, especially hydrocephalus. Putting aside altogether the striking fact that the dangerous disturbance of dentition is proceeding at the same time, it may be allowed that hydrocephalus and the other diseases mentioned may and often do occur after or during protracted lactation ; but they happen quite as frequently, and indeed more so, where a child has been brought up by hand, without the breast at all ; or where it has been badly fed, or over-fed, whilst still suckling. In all the cases of mothers who have nursed their children for two years and upwards, in the class of life alluded to by Dr. Morton, it may be, perhaps, fairly assumed, from the known habits of the parents, that the children have been fed at the same time, and generally fed upon exactly the same sort of food as would be more adapted to older children. "The child eats whatever we eat" is the common expression, though the child is still allowed to apply to the breast at pleasure, to prevent the chance of a fresh pregnancy. Many children, particularly in the higher classes, where hired wet-nurses are employed, are kept for a long time at the breast because they are backward with their teeth, have had their bowels disordered by a premature attempt at weaning, or because they are in delicate health ; but if hydrocephalus supervene in such instances, it is quite as likely that the previous disordered health may have been the cause, as the protracted lactation. In savage nations, in many parts of America, the east, and the polar regions, it is the constant custom for mothers to suckle their infants for two years at least, and without any of the pernicious consequences which Dr. Morton has imagined. (See Edinburgh Medical and Surgical Journal, No. 110.)

It is certainly true, that if the mother's health be impaired by undue lactation at either an early or a late period, the child will suffer from defective nutrition, but in no other manner.

[According to M. Desormeaux (Art. Lactation, in *Dict. de Médecine*, xxii. 425, Paris, 1838,) some women are able to continue suckling almost indefinitely, provided the child be put to the breast. It is not uncommon, he says, in France to see nurses suckle three children in succession, comprising a period probably of from 30 to 36 months; and cases are not rare of women who have suckled their children for four years, and four years and a half. He himself saw a nurse from Normandy, who had suckled several children successively on the same milk for upwards of five years; and a lady, worthy of all credit, informed him, that she knew a woman who nursed five children in succession, so that her lactation continued at least seven years.

It has been a common opinion, that when menstruation recurs during lactation, the milk of the nurse is unfit for the perfect nutrition of the child. M. Gendrin would on no account permit a woman to continue nursing after the catamenia had returned. The subject has been recently investigated by M. Raciborski (*Dublin Medical Press*, Aug. 2, 1843, cited in *Amer. Journ. of the Med. Sciences*, Oct. 1843, p. 455,) whose inferences are as follows:—contrary to generally received opinions, the milk of nurses who menstruate during suckling does not differ sensibly in physical, chemical, or microscopical characters from that of nurses whose catamenia are suspended ; — the only difference which can be detected between the kinds of milk is, that, in most cases, the milk of menstruating nurses contains less cream during the menstrual period than in the intervals; hence arises the bluish appearance presented occasionally by such milk; and he concludes that a nurse should never be rejected merely because she menstruates.]

Dr. Marshall Hall has well described the state of disorder of the general health in females, which is induced by exhaustion of the frame, arising from protracted lactation, or from the original powers not having been equal to the continual drain on the system. One of the earliest symptoms of failure is a dragging sensation in the back, when the child is in the act of sucking, and an exhausted feeling of sinking and emptiness at the pit of the stomach afterwards. The appetite fails gradually, but entirely ; there are thirst, a dry tongue, a quick feeble pulse; costive bowels, headach, with giddiness, lightness, and failure of sight. The skin is hot and cold alternately ; there are profuse night-perspiration; generally leucorrhœa, great debility, and emaciation. The memory is impaired; the spirits are weak, irritable, and depressed. [Occasionally, too, aphthous stomatitis occurs, and it would seem to occur more frequently in some localities than in others: (see Aphthæ.)] Symptoms resembling phthisis will sometimes come on, and mania is not an unusual result. Though much may be done in the first instance by the proper use of tonics, cold or sea bathing, change of air, a regulated diet, and local applications, to restrain the leucorrhœa; and though we may now and then effect a portion of good by partially feeding the child, yet the quickest and most effectual remedy is to wean the child. The different symptoms resulting from the exhausting process require appropriate treatment, according to

circumstances; but all treatment will generally fail, unless we remove the cause of exhaustion.

Before leaving the subject of lactation, it may be remarked that males have also the organs for supplying milk, in a dormant state, which under peculiar circumstances have been excited into action, and have supplied milk in abundance, sufficient to suckle children. Instances have been given in recent times by Humboldt and Captain Franklin, and many others are on record. Very old women* and virgins have also had milk in considerable quantities, the nipples in all these cases having been frequently stimulated by the contact of the child's mouth purposely applied.

[Several instances not only of very old women and virgins but of men having suckled children have been given by the writer in his *Human Physiology*, 5th edit. ii. 436, Philad. 1844.]

It is by no means uncommon to meet with newly-born infants, of either sex, who have their breasts turgid with a milk-like fluid, which is dispersed with difficulty.

C. Locock.

LARYNGITIS. — Of inflammations of the larynx there are many varieties, to which we mean briefly to allude before we enter upon a description of that formidable disease which has of late years obtained the title of laryngitis, and is the proper subject of this article.

Beginning with the slighter inflammations, we may, 1st, advert to that affection of the membrane lining the larynx, which is distinguished by hoarseness, or complete loss of voice, and by slight cough, an affection which, arising from exposure of the body, or part of it, to a current of cold or damp air; from partial or general wetting; or from an incautious laying aside of some article of dress, especially during changes of the weather, is so slight, as seldom formally to be brought under the observation of the physician.

2dly. Similar symptoms not unfrequently occur in connection with common sore throat (*cynanche tonsillaris*), and for the most part they also form a case for domestic prescription, unless the inflammation is so considerable as to threaten suppuration.

These two affections are chiefly prevalent about the beginning of winter and in the spring, and for the most part yield to confinement to the house for a day or two, and the antiphlogistic regimen. The latter affection, like the former, is of little importance, unless considered in connection with laryngitis, which has sometimes commenced like an ordinary sore throat attended with hoarseness; or unless it give rise to chronic disease of the affected part; for it is observable of both these slight inflammatory attacks, that when neglected, or when, from exposure to frequent vicissitudes of temperature, to foggy and cold weather, or to the night-air, they are from time to time renewed, a state of permanent irritation is sometimes produced which is indicated by hoarseness, slight muco-sibilant inspiration, and cough, and by some difficulty of swallowing; symptoms which, especially in persons advanced in life, end in chronic laryngitis, a disease always intractable and often fatal. In these attacks, relief, if sought in time, may in general be obtained by bleeding, especially topically, and blistering; by a course of calomel and ipecacuanha, or calomel and antimonial powder, one grain of each given three times a day, and continued until the gums become slightly affected by the mercurial; by pure air of moderate and equable warmth; and rest and quiet.

3dly. Sometimes the membrane of the larynx is inflamed in gastric fever, and in various fevers of the exanthematous order, especially in small-pox, measles, scarlatina, and erysipelas, fevers which we apprehend are all essentially gastric. In small-pox, the epiglottis and larynx are often inflamed and beset with pustules, from which very great distress arises. In the beginning of measles, inflammation of the upper part of the windpipe is so considerable as to give rise to an attack which, for a short time, advances with all the violence of croup. In the winter of 1807, and more especially in the spring of 1808, when measles were epidemical in Edinburgh and the neighbourhood of that city, and of so unfavourable a kind that we witnessed the death of more than 100 patients in the course of a few months, the disease corresponding with the putrid measles of Watson, (Med. Obs. and Inquiries, vol. iv. p. 132,) not only was the larynx often affected before the efflorescence took place, but in several instances after the rash had disappeared it became inflamed; in all which cases, to the best of our recollection, the patients died. In one dissection which we procured, of laryngitis after measles, the following were the appearances discovered. The investing membrane of the epiglottis was considerably thickened, particularly at its edges; such also was the state of the membrane of the glottis; the sacculus laryngeus was nearly obliterated, and, below the sacculus, ulceration had taken place. When the epidemic commenced, bleeding was often useful, but after it had continued for some time, and had become more fatal, the attending fever being typhoid, bleeding appeared injurious; indeed we then observed that scarcely a child recovered which had been bled, so that bleeding was not had recourse to when the larynx became inflamed. Nor were blisters applied, most blistered surfaces having a strong tendency to run into ulceration and gangrene. Were we again to be called to such cases, we would recommend immediate change of dwelling, a remedy not yet duly appreciated in acute diseases; an emetic and calomel, with small additions of opium.

We have frequently known inflammation in scarlatina and in some forms of cynanche to affect the fauces, whereon perhaps a plastic membrane was formed, and to ascend into the nares and descend into the windpipe. Several soldiers of a militia regiment, stationed at Woolwich, were daily brought into the general hospital with scarlatina. The disease was unusually fatal. One

* A very interesting account is given (in the Medico-Chirurgical Review, for July 1832) by Dr. Kennedy of Ashby-de-la-Zouch, of Judith Waterford, of that place, and now alive, with milk still in her breasts at the age of eighty-one: the summary may be given in Dr. Kennedy's own words. "Here, then, are the remarkable circumstances of a woman who menstruated during lactation, who suckled children (many not her own) *uninterruptedly* through the full course of *forty-seven* years (three years of which time she was a widow), and in her eighty-first year has a moderate but regular secretion of milk."

of these patients, who had been only a few hours in the hospital, died after symptoms which the surgeon on duty thought proper to investigate by dissection. He cut out the trachea, and found it lined with a membrane as in croup. The preparation was preserved, and afterwards presented to the writer of this article by his late friend Dr. Rollo, surgeon-general to the artillery: an engraving of it was given by the writer in his work on the "Pathology of the Membrane of the Larynx." At page 37 of the same work, will be found an account of two cases of inflammation of the larynx, one occurring about the eighth or ninth day of fever in a girl eight years of age, who was relieved by bleeding; the other in a girl of eleven, in whom an attack of bilious remittent fever was ushered in by laryngeal inflammation. A fatal case of laryngitis occurring during apparent convalescence from remittent fever, published in the first volume of the Transactions of the Physico-Medical Society of New York, was republished in the Medico-Chirurgical Review for April, 1827.

In erysipelas the fauces are often inflamed, and the inflammation extends to the larynx, in which case the respiration resembles that of croup, and the disease is generally fatal. A female thirty-four years of age, had been in the hospital at Cochin for disease of the heart, when, on the 23d of February, she was seized with violent rigor; 24th, erysipelatous eruption of the face with febrile re-action; 25th, 26th, the erysipelas was extended to the hairy scalp and to the neck, eyes closed; 27th, acute pain in the throat, difficult deglutition, respiration impeded; 28th, swelling and inflammation in the anterior part of the throat; inability to expectorate; suffocation threatened. March 1st, swelling of the neck enormous —asphyxia—death.

Dissection.—The mucous membrane lining the mouth, larynx, and pharynx, red and inflamed. The epiglottis and its ligaments thickened; the rima glottidis nearly annihilated by the swelling and by tough mucus. The cellular tissue of the larynx, face and neck injected, red, and œdematous; the lungs sound. (*Bouillaud.*)

4thly. The larynx is often inflamed in those diseases in which the inflammation extends over the whole of the mucous membrane of the lungs. In common and also in epidemic bronchitis, the inflammation, apparently commencing in the Schneiderian membrane and fauces, often affects the larynx in its descent into the bronchi. The membrane of the larynx is also liable to be affected in those varieties of chronic bronchitis, which, according to the season or age at which they occur, or according to the symptoms of the attack, have been termed winter cough, catarrhus senilis, suffocative catarrh, or peripneumonia notha. In pertussis, inflammation often obtains in the mucous membrane of the larynx as well as in that of the trachea and bronchi. Lastly, in croup, the symptoms referable to inflammation of the larynx are so obvious and remarkable as to have exclusively engrossed the attention of most observers, leading them to overlook proofs, scarcely less equivocal, of an inflamed condition of the bronchi.

5thly. We have known many cases of inflammation of the glottis arising from an accident, to which the children of the poor are liable. Slatternly mothers often permit their children to drink from the spout of the tea-kettle, and the children are thus led to a habit which, if the kettle should happen to contain boiling water, may prove fatal. The symptoms produced by this accident are inflammation and vesication of the fauces, difficult breathing, audible inspiration, whispering voice, leaden countenance, watery eyes, and cold extremities — symptoms which we were wont to think were as much dependent upon bronchitis as upon inflammation of the glottis; but a dissection published by Dr. Marshall Hall, in his satisfactory account of this affection in the twelfth volume of the Medico-Chirurgical Transactions, would lead to a conclusion that the inflammation does not extend even to the trachea. We have been accustomed to treat this affection by bleeding, blistering, and a preparation of calomel and ipecacuanha. Our confidence in bleeding is not, however, very great. The children soon acquire that peculiar expression which livid paleness with œdema imparts, when asphyxia, in an advanced state of bronchitic inflammation, is impending, a state which contra-indicates free bleeding. Bronchotomy is recommended by Dr. M. Hall, and this operation his view of the case would amply justify. He also recommends scarifying the epiglottis. Probably small doses of opium, given at an interval of two or three hours, would be useful, as they generally are in burns attended with much suffering. In the third volume of the Dublin Hospital Reports there is a case given by Dr. Burgess, of a girl of three years of age, who drank boiling water from the pipe of a tea-kettle, by which great swelling of the parts immediately ensued, thereby preventing deglutition and impeding respiration. In about two hours after the accident, in looking into the mouth, it appeared as if a large piece of raw flesh had been forced into the fauces, and had completely filled up the passage. Respiration was performed with very great difficulty, and was rapidly becoming more laborious,—in fact the child appeared to be dying, when bronchotomy was performed, by which life was saved.

6thly. Inflammation of the mucous membrane of the larynx sometimes arises when the system is under the influence of mercury. We think we have seen inflammation extending to the windpipe in severe cases of mercurial glossitis, and hence we are unwilling to reject, as one of the species of laryngitis, that caused by mercury. But we are not satisfied that the cases of alleged mercurial laryngitis, which have been recently published, did not owe their origin to other influences, such as lues venerea, or exposure to cold, rather than to the mercury.

7thly and 8thly. There are yet two inflammatory affections of the membrane lining the larynx which must be briefly described, in order to complete this part of the subject: these are scrofulous inflammation of that portion of the mucous membrane, and inflammation symptomatic of secondary syphilis.

Scrofulous inflammation is an affection of a very dangerous nature, not, as we apprehend, generally accompanied with tuberculated lungs

This affection is not confined to youth or adolescence; sometimes it appears at or after the meridian of life, as the commencement of a very chronic variety of phthisis, which some physicians have imagined depends upon indigestion, and is to be cured by blue pill, &c. We have frequently witnessed this affection in an acute form in persons who had abandoned themselves to the habitual use of ardent spirits, in *muddlers*, as they are called, who drink at all times, but seldom to complete intoxication. Such patients lose their appetite; become emaciated; usually have a patchy purplish complexion; gradually acquire a dry hard cough, which at first appears nothing more than an aggravation of that cough observable in drunkards, which is attended with white and scanty expectoration, and is followed, especially in the morning, by retching or even vomiting of a little clear ropy fluid. If we examine these patients, we shall find the pulse accelerated, the tongue and fauces florid, the former glazed. This disease is always fatal, but generally not until purulent expectoration, colliquative diarrhœa, and night sweats, have existed for some time. It often is to be met with in publicans, and such as are engaged in the occupation of vending ardent spirits. It is attended with a sense of exhaustion, a depression of mind, a fear of death, and a consciousness of the disease being self-produced, which it is most painful to witness. The patient may, in the commencement, derive some advantage from change of air, exercise on horseback, very small topical bleedings, not more than three or four leeches being applied, followed by counter-irritants and light bitters. The bowels must be properly regulated, avoiding all medicines which lower the strength; and a mild alterative pill may be given for ten days or a fortnight, namely,

℞ Pilulæ hydrargyri, scrupulum.
Pulveris conii, scrup. ii.
Ipecacuanhæ, gr. xv.

Ammoniaci contriti, sesquidrachmam, M. et divide in pilulas xl. Sumat duas mane et meridie; superbibendo poculum lactis asinini.

Milk, shell-fish, broiled, tender but lean meat, and vegetable jellies will form the most suitable nourishment.

The more common form of scrofulous inflammation of the larynx and trachea belongs to youth, and occurs in those families of which the members are liable to consumption. It has seemed to us often to arise from night-air and fatigue, especially when these causes operate during a season of mental anxiety and over-exertion. This is a frequent disease with those wretched females who frequent the streets of our cities in the night, and their obscene haunts during the day. The hue which may be observed on their cheeks is not always the glow of intemperance or of shame, nor yet the factitious blush of effrontery, but is often the crimson of a consuming hectic, which is rapidly hurrying them from misery to misery. It is little known how large a portion of the tenants of the brothel actually labour under consumption: but the subject is too horrible to be pursued.

At first the disease is attended with a dry barking cough, a single bark, often supposed to be a stomach cough; but the symptom which is most distinctive of this very treacherous complaint, and which in consumptive families ought ever to excite the liveliest apprehension of danger, is a change in the sound of the voice, which the patient can no longer extend without difficulty. It is slightly raucous, and acquires that hollowness which, both as if proceeding from a vault and in reference to its tendency, is not unaptly called sepulchral. When, the attention being arrested by the cough and the sound of the voice, which often have existed for many weeks or even months before they become objects of regard, we more closely examine the patient, we shall find that there is some uneasiness in the region of the larynx, or in the superior part of the thorax; a degree of quickness of the pulse is discoverable, as also some emaciation and decay of the strength, but the latter so slight as to have escaped notice. Indeed so insidious is this disease, that in many instances it has passed undiscovered until some acquaintance, who had not for a considerable time seen the patient, discerning a great change in his looks, expresses his apprehension. Then the truth, in all its nakedness, flashes on his alarmed relatives, and a physician is obtained who detects the nature of the disease by discovering that there are irregular chills followed by heats and perspirations, and confirms all their fears. The patient soon loses the power of extending his voice; he can only speak in a whisper; his cough becomes stridulous, his expectoration purulent, and laryngeal or tracheal consumption is incurably established. If a patient, fortunately for himself, should in the commencement of his disease be visited by a person possessed of medical skill, his life may sometimes be saved. In the treatment of this complaint, if the disease should not have reached the suppurative stage, we must disregard the diathesis, and address ourselves to the local affection. First, we must apply leeches to the upper part of the sternum; we prefer three or four leeches every third or fourth day to a greater number; secondly, the tartar-emetic ointment (taking care that it does not reach the leech-bites) to the sides of the larynx, first to one side and then to another; thirdly, we must give the solution of tartar-emetic (so as to excite slight nausea) with the addition of nitre.

℞ Antimonii tartarizata, gr. duo.
Nitratis potassæ, scrup. ii.
Aquæ distill. unc. sex: M. et divide in haustus sex. Sumat unum, ter, quaterve de die.

Lastly, a diet consisting of milk, farinacea, and fruits, will be necessary. This plan may be followed for eight or ten days; if without efficacy, new measures must be tried, as change of air and scene, and restoratives, such as a return to the use of animal food, a glass or two of claret, and sponging the surface with very diluted nitro-muriatic acid, which may also be taken internally. If the expectoration be considerable, a drachm of Riga balsam in a glass of water may be taken three times a day, or the following draught:

℞ Tinct. benzoini compositæ, ʒi.
Mucilaginis acaciæ, ʒii.
Syrupi papav. albi, ʒi.
Aquæ cinnamomi, ʒvi. M.

together with such treatment as would apply to impending laryngeal or tracheal phthisis.

There are certain cases of scrofulous inflamma-

tion of the windpipe that are invariably overlooked in the first stage, of which the first symptoms detected are round and pretty deep ulcers in the fauces. The affection of the larynx so commencing, according to our observation, always ends in phthisis.

The syphilitic inflammation of the larynx, like the last variety, is seldom discovered in its very beginning. This disease is introduced by anomalous symptoms of constitutional disorder, and an obscure febrile state. The patient's expression appears altered and anxious, his complexion pale or mixed, his skin opaque and, as it were, dirty, his eyes hollow, the tarsi slightly inflamed; some degree of emaciation takes place; then the voice becomes husky. These symptoms will naturally suggest that line of inquiry which we adopt when we are endeavouring to detect a syphilitic taint; and here it will not be irrelevant to observe that a change in the sound of the voice, whenever it accompanies a cachectic state of the body, demands the utmost attention,—attention which will sometimes be rewarded by enabling us to discover the approach of a disease that would shortly assume a hopeless expression. In syphilitic inflammation of the larynx, when the head is suddenly turned to a side, uneasiness will be felt in the organ, which, when pressed, feels tender. The patient suffers much from a stridulous cough, attended with little or no expectoration. These symptoms being neglected, ulceration of the membrane of the larynx next ensues, which may be discovered by difficult and suffocative inspiration and cough, by purulent expectoration, and by unequivocal hectic, attended with great irritability of the nervous system, and, lastly, by permanent loss of voice. In the commencement of this affection, we must endeavour to subdue the inflammation by means of leeches, blisters, and the antiphlogistic regimen. Then we must give the muriate of mercury in decoction of sarsaparilla, and employ mercurial fumigations.

In this manner, with the help of change of air, a remedy often of surprising efficacy in specific inflammations, a cure may sometimes be accomplished; but syphilitic inflammation of the larynx, which we apprehend will be most likely to occur in strumous habits, will, in general, like the proper scrofulous inflammation, terminate in laryngeal consumption, unless a termination should take place in the inflammatory stage, such as was exemplified in one of Bouillaud's patients, who died of suffocation so early as the fifth day, the cellular membrane being so thickened, infiltrated, and gorged, as almost to obliterate the rima glottidis; and on the left side of the larynx an ulceration being formed with the characters of chancre. (Med. Chir. Journ. for July, 1825, p. 206.) When syphilitic ulcers exist, they will generally be found in the sacculi laryngis. We have, in a specimen of diseased larynx, seen fimbriated excrescences in the glottis, which were probably syphilitic, but we were not able to obtain a history of the preparation.

As we learn from an ably written paper by the late Mr. Wood, in the seventeenth volume of the Medico-Chirurgical Transactions, on the effects of inflammation of the larynx, that a patient lately died in St. Bartholomew's Hospital, of a disease of the larynx, which was discovered after death to be cancerous; and as Dr. Monro, in the 2d volume of his Outlines of Anatomy, informs us that he has seen in some cases the arytenoid and thyroid cartilages thickened and covered by a scirrhous substance, by which the glottis was straitened; it is probable that our successors in pathology, when facts accumulate, will add a *ninth* species, viz. scirrhous inflammation of the larynx, to the foregoing catalogue of diseases of that organ.

We proceed to the consideration of laryngitis, which is a more suitable designation for the disease now under review, than *angina œdematosa*, as applied to it by some authors: it has been well observed that "the term *œdematosa* is unnecessary, as œdema constitutes no fundamental character of laryngitis, but is an effort or consequence of inflammation of the affected organ," (Med. Chir. Journal for July, 1825, p. 206,) in what manner soever excited.

Of laryngitis, it is true, notices and cases were previously published, but the disease was not generally understood prior to the publication, by Dr. Farre, of a valuable paper on cynanche laryngea, in the third volume of the Medico-Chirurgical Transactions.

Our knowledge will often be advanced by examining a specimen of a disease before we apply ourselves to the study of its general history. We therefore beg to call the attention of the reader to a case of laryngitis in every way interesting, but especially so to the pathologist, as being the first accurately reported history of that disease which, as far as we know, is to be found in the annals of medicine.

"Some time on the night of Friday, the 10th December, 1799, having been exposed to rain on the preceding day, General Washington was attacked with an inflammatory affection of the upper part of the windpipe, called in technical language cynanche trachealis. The disease commenced with a violent ague, accompanied with some pain in the upper and fore part of the throat, a sense of stricture in the same part, a cough, and a difficult rather than a painful deglutition, which were soon succeeded by fever and a quick and laborious respiration. The necessity of bloodletting suggesting itself to the General, he procured a bleeder in the neighbourhood, who took from his arm in the night, twelve or fourteen ounces of blood. He could not by any means be prevailed on by the family to send for the attending physician till the following morning, who arrived at Mount Vernon at about eleven o'clock on Saturday. Discovering the case to be highly alarming, and foreseeing the fatal tendency of the disease, two consulting physicians were immediately sent for, who arrived, one at half after three, and the other at four o'clock in the afternoon. In the mean time were employed two pretty copious bleedings, a blister was applied to the part affected, two moderate doses of calomel were given, and an injection was administered, which operated on the lower intestines; but all without any perceptible advantage, the respiration becoming still more difficult and distressing. Upon the arrival of the first of the consulting physicians,

it was agreed, as there were yet no signs of accumulation in the bronchial vessels of the lungs, to try the result of another bleeding, when about thirty-two ounces of blood were drawn, without the smallest apparent alleviation of the disease. Vapours of vinegar and water were frequently inhaled; ten grains of calomel were given, succeeded by repeated doses of emetic-tartar, amounting in all to five or six grains, with no other effect than a copious discharge from the bowels. The powers of life seemed now manifestly yielding to the force of the disorder; blisters were applied to the extremities, together with a cataplasm of bran and vinegar to the throat. Speaking, which was painful from the beginning, now became almost impracticable; respiration grew more and more contracted and imperfect, till half after eleven on Saturday night, retaining the full possession of his intellect, when he expired without a struggle. He was fully impressed at the beginning of his complaint, as well as through every succeeding stage of it, that its conclusion would be mortal; submitting to the several exertions made for his recovery, rather as a duty than from any expectation of their efficacy. He considered the operations of death upon his system as coeval with the disease; and several hours before his death, after repeated efforts to be understood, succeeded in expressing a desire that he might be permitted to die without further interruption. During the short period of his illness, he economized his time, in the arrangement of such few concerns as required his attention, with the utmost serenity; and anticipated his approaching dissolution with every demonstration of that equanimity for which his whole life had been so uniformly conspicuous."*

The violent ague with which this case commenced was doubtless the rigor of incipient inflammation; the pain in the upper and fore part of the throat, the sense of stricture in the same part, and the labour of respiration, showed that inflammation was seated in the larynx. The difficult deglutition arose from the state of the tonsils, in which probably the inflammation commenced. The inflammation did not descend into the bronchial vessels of the lungs, wherein we are told there were no signs of accumulation. It may be inferred, therefore, as will be apparent from the sequel, that this was a genuine specimen of laryngitis.

Laryngitis generally arises from exposure of the body, or a part of it, to cold or wet, or from sudden transitions of temperature. It affects those persons who are liable to cynanche tonsillaris, and often commences as one of their accustomed attacks; and hence the patients are seldom alive to danger until a feeling of suffocation convinces them that their illness is one of unusual severity. In the Richmond Surgical Hospital, House of Industry, Dublin, we saw a case of inflammation of the larynx, which commenced in the tonsils, and was by malpractice extended to the larynx. The patient was a robust young man; his face was much flushed, his pulse quick. He was completely hydrophobiac. When he tried to swallow, the effort was followed by extraordinary difficulty of inspiration, and every attempt to articulate was productive of a sense of strangling. There were pain and great tenderness on pressure on either side of the pomum Adami. He was attacked, two days before he entered the hospital, with cynanche tonsillaris, when an old woman, partial to stimulants, as such practitioners generally are, rubbed the inflamed tonsils with pepper and salt, and immediately difficult deglutition came on, which was followed by constriction of the glottis. He fell under the care of an excellent surgeon, the late Mr. Todd, who soon restored him to health by copious general and local bleeding.

If, when the throat first becomes sore, the patient is examined, probably the uvula will appear inflamed, and the tonsils and arch of the soft palate redder than natural; and in some few instances exudations of coagulable lymph will be seen on those parts; the tongue perhaps is swelled; the face flushed; the pulse frequent, full, and hard; and the skin hot. The breathing soon becomes affected; the inspiration "is long in being completed," audible, and as if the air were drawn through a dry and narrow reed; the patient points to the larynx as the seat of uneasiness; he frequently coughs, and the cough is very peculiar in sound, not so ringing as that of croup, but harsher and more stridulous, and attended with scanty, viscid, and transparent expectoration. Pain is sometimes complained of in the chest. The voice, at first acute and piping, gradually becomes thick, then hoarse and whispering, and at last it is completely suppressed. There is sometimes great difficulty in swallowing, from the epiglottis ceasing to perform its valvular office, whence it happens that, when the patient begins to drink, a portion of the fluid escapes into the larynx, and produces a fit of coughing, which seems to threaten instant suffocation.

Laborious respiration and an inadequate supply of air before long affect the appearance of the patient. His expression becomes full of anxiety; his countenance pallid; his lips leaden; his eyes protruded and watery; his pulse is quick, feebler, and less uniform; and the surface of his body colder. Sometimes the integuments which surround the larynx, especially in the fore part of the neck, are swollen. In a case operated upon by Mr. Macnamara of Dublin, the trachea was laid bare at a depth of two inches and a half below the surface, to such an extent had the integuments of the neck become œdematous. The patient is restless and apprehensive, often changing his position, in the vain hope of obtaining relief; walking or rather staggering to and fro, or from one room to another, in great distress: feeling that he is on the point of suffocation, he cannot be ignorant of the danger to which he is exposed; hence he is willing to submit to any means of relief, and is impatient of delay.

In this stage of the complaint the patient seldom sleeps for many minutes at a time; when he begins to doze, he starts up in a state of the utmost agitation, gasping for breath, every muscle being brought into action which can assist respiration, now a convulsive struggle. He is quite enfeebled, becomes delirious, drowsy, and at last comatose,

* This account is dated Alexandria, Vir., Dec. 21, 1799, and signed by Dr. James Craik, attending physician, and Dr Elisha E. Dick, consulting physician.

the circulation being more and more languid, and he dies on the fourth or fifth day of the disease, or even earlier. Instances have come to our knowledge in which the disease has terminated fatally within twelve hours, (one of Dr. Armstrong's patients died in eight hours, and another in seven;) and therefore, if a person dies suddenly in the night, who had complained on the foregoing day of sore throat, laryngitis may be suspected as the cause of his death. Instances have also come under our observation, in which the disease has lasted three or four weeks, of which the following case is an example.

We have inserted the first recorded case of laryngitis, that of General Washington; and we beg to insert the first case of the disease recorded as such.* In so doing, the reader will obtain a glimpse of the second Monro, who, at a time when the most eminent of his contemporaries in England were ignorant of its existence, perfectly understood and explained to the writer of this article the nature of laryngitis.

Mr. A. æt. forty-three, robust and corpulent, in the spring and summer of 1805 was for three months under a mercurial course for secondary symptoms of syphilis. In spring 1806, he was affected with fever and pains in his limbs. In July 1806, he laid aside his flannel shirt, and thought he caught cold. July 10th, severe fits of coughing in the night; 11th, 12th, 13th, troublesome nights from the cough. V. S. ad ℥xvi. 14th to 19th, emetic, squills, opiates; 20th, respiration not quickened, but difficult, constriction felt in the larynx; long-continued fits of stridulous cough; tongue white and swelled; pulse 120; by an effort he can completely inflate the lungs without raising a cough. On this day the patient was first seen by the writer of the case, at whose request Dr. Monro was called into consultation, whose opinion was *that the symptoms arose from inflammation and thickening of the mucous membrane of the windpipe.* Twelve leeches to the left of the windpipe, and a blister to the right, pulv. jalapæ comp. ℥ss. calomelanos gr. v. July 22d, during the night he slept not many minutes at a time; cough threatening suffocation; expectoration of clear ropy mucus; hissing inspiration; tongue furred and swelled; evident fulness as well as tenderness on the left side, and in front of the thyroid cartilage, which is painful when the head is turned. When in bed his head is low, and thrown to the left side; when sitting, his chin is projected; countenance anxious. Opinion: *as the disease appears to be confined to the upper part of the windpipe, it was resolved, should suffocation be imminent, to perforate the larynx between the thyroid and cricoid cartilages.*— Leeches, blister, steam of warm water and vinegar. July 24th, miserable nights; often on the point of suffocation; pain on pressure in every part of the trachea, pulse 128; tongue more swelled. July 27th, in the last three days a pound of blood was drawn each day. The first blood sizy and cupped. Laudanum produced sleep, but he awoke gasping, dyspnœa being then more severe. Sometimes he started from his chair, and staggered from one room to another; then his face was quite livid; his pulse, an hour after a paroxysm, was 136. Tongue swelled, and indented from the impression of the teeth. Emetic of ipecacuanha proved nearly fatal. When he began to vomit, his inspiration was interrupted and crowing; his face was pale, and his lips livid. Gr. ii. calomelanos ter quotidie. Evening, haustus cum tinct. opii et vini ant. gutt. x. August 4th, sickness after the evening draught, which lasted all night. At 7 A. M. breathed with great difficulty; extreme cold. He was taken out of bed and seated on a sofa, supported with cushions and pillows, after which his head fell upon his breast, and he ceased to respire. When his head was raised, respiration was resumed, but it was stertorous, and his complexion was changed from the purple of imperfect respiration to the paleness of a cadaver. Bronchotomy was performed without effect; he died in about two hours after the operation. We were not permitted to examine the body, but concluded that death arose from closure of the rima glottidis, owing to *thickening of its lining membrane.*

At one time it was conjectured that this case

* Abridged from the Pathology of the Larynx and Bronchia, by J. Cheyne, M. D. Edin. 1809.

May we be permitted to introduce Dr. Monro to the student of pathology as a physician worthy of the closest imitation. In his writings we have somewhat too much of the ardour of controversy, into which he was betrayed in support of his reputation as a physiologist, ungenerously assailed; but in the common intercourse of professional life he was scrupulously correct in conduct, and in his manners urbane. He was a strict economist of time,—a man of industry and order. His mind was unceasingly occupied in the acquisition of knowledge, so that no allurement, not even the pleasure of his garden, for which he had a genuine relish, was permitted to seduce him from his daily task of recording the results of his observation, by carefully arranging and registering the facts which he judiciously collected; and hence, after he had passed the common period of life, when between his seventieth and eightieth year, he was still to be found in his study, with his case-book before him, adding to his stock of pathological knowledge. In the investigation of disease he could not be viewed without admiration. His digested experience, his keen observation, and the excellent method of inquiry which he pursued, rendered him a personification of medical sagacity, and enabled him, in consultation, to tower above the great competitors of his youth and age, the one a man of genius, the other of talent—Cullen and Gregory, who were children compared with Monro in the power of discovering the nature and predicting the course of an obscure and uncommon disease. He was remarkable for the possession of tact, employing the term not merely as expressive of discrimination, but also of that quality which, in the exploration of diseases in the thorax, abdomen, and pelvis, enables the physician, by manual examination, to detect the nature of the altered structure of the organs contained in these cavities. Monro, in his inquiries, brought not merely his touch, but all his senses to his aid in an extraordinary manner. Long before the time of Laennec he availed himself of the aid of auscultation (immediate) in ascertaining the existence and nature of diseased conditions of the heart. We have known him sit for a long time, with his ear applied to the thorax, deriving information from a mode of inquiry at that time peculiar to himself. Finally, though remarkable for caution, he possessed great decision of character, of which his practice, never rash, but often extremely bold, afforded sufficient evidence. The therapeutic agents which he employed were skilfully combined, and while mere effect was despised by him, while

> "His vigorous remedy displayed
> The power of art without the show"—

nothing was omitted in weak compliance with the prejudices of his patient. This sketch will be pardoned by all those who think that, even with advancing age, there ought to be no abatement of zeal in the cultivation of professional science; that improvement in all things is promoted by placing models of excellence before the eyes of the student; and that an expression of gratitude is seemly. The writer, having derived many useful lessons from studying the character of Monro, has never lost an opportunity of paying an humble tribute to his memory. It appears surprising that this great pathologist should have been allowed to retire from the theatre of his usefulness without receiving one valedictory plaudit.

was connected with syphilis; but if such a complication had existed, it is probable that the inflammation would, in four weeks, have reached the ulcerative stage, of which the expectoration afforded no evidence. This case, with several others which fell under our care, induced us to attempt a definition of the disease in the following terms. "Pain in the larynx not very acute, unless on pressure; some degree of fulness externally; a change in the sound of the voice, difficult and even crowing inspiration, but slow rather than quick; an altered, sometimes stridulous voice; fits of suffocative coughing; and all those symptoms which arise from obstructed circulation in the lungs." (Vide Pathology of the Larynx, p. 161.)

Causes.—Persons advanced in life are more liable to laryngitis than the youthful; and of the former the disease most frequently occurs in such as are liable to indigestion, connected with a disordered condition of the liver. Several of our patients had been habitually intemperate. The exciting causes of laryngitis, as we have already mentioned, are such as usually are productive of common cynanche or catarrh, the principal being exposure to cold.

Prognosis.—In some new cases of laryngitis the inflammation recedes, and the disease terminates favourably. This favourable change we may presume is taking place when we discover that the swelling of the epiglottis is subsiding, that the difficulty of breathing and pain of the larynx are abating, and when freedom of expectoration is restored, and deglutition becomes easy. On the other hand, the danger increases with an increasing struggle of breathing. Paleness and lividity of the complexion, a prominent watery eye, and lethargy or stupor, are symptoms which indicate great urgency of danger. It may fairly be affirmed that laryngitis is the most fatal of the phlegmasiæ; consequently the prognosis, in every stage of the disease, must be delivered with the utmost caution. "Of seventeen cases of laryngeal angina observed by Bayle during six years, only one ended favourably."

Diagnosis.—The diseases which are most liable to be mistaken for laryngitis are—

1. Ossifications and caries of the cartilages of the larynx. This state of these bodies gives rise to extensive ulceration, of which the diseased cartilage is the centre. This affection is often of slow growth, beginning with uneasiness in the region of the larynx, followed by hoarseness; then occur cough, difficulty of breathing, which is croaking, sibilous, and in paroxysms; and difficulty of swallowing; purulent expectoration, which is often of extraordinary fetor; sometimes diseased portions of cartilage on which the fetor depends, being expectorated. We learn from Dr. Monro's Outlines of Anatomy, that the cartilages of the larynx, especially the thyroid, and sometimes even those of the trachea, are occasionally found ossified. In examining the body of an old man, who for the last six years of his life had been subject to a severe and almost unremitting cough, "I found," says Dr. Monro, "the cartilages of the larynx ossified, a considerable quantity of viscid mucus within the trachea, and its internal coat thickened, spongy, and red. In such cases the mobility of the different component parts of the larynx being lessened or destroyed, the voice becomes much feebler; and there have been instances, as I have been informed by my father, of these morbid ossifications exfoliating internally, and portions of the bony matter expelled by coughing." By a patient labouring under disease of the cartilages of the larynx, who was under the care of Dr. Colles of Dublin, one of the arytenoid cartilages was expectorated; and Dr. Hunter, as we learn from Dr. Baillie, "knew an instance in which the cricoid being converted into bone was separated by exfoliation, and afterwards coughed up." Abscesses thus formed sometimes burst into the œsophagus, sometimes into the cavity of the windpipe, and sometimes they open externally. When the patient escapes sudden suffocation, this disease, which admits of treatment similar to that of simple laryngitis, usually ends in hectic fever. In general it is not attended with inflammation of the epiglottis, and instead of terminating within four or five days, its course is tardy. To this disease, rather than to simple laryngitis, we apprehend belonged the case of the Right Hon. Isaac Corry, as detailed by the late amiable and accomplished Dr. Edward Percival, in the fourth volume of the Medico-Chirurgical Transactions. In Mr. Corry's case, as we learn from Dr. Colles, who was one of his attendants, the epiglottis was in a natural state, and the rima glottidis little if at all reduced in its capacity. Of the same nature appears to have been the first of Mr. Lawrence's cases, published in the sixth volume of the Medico-Chirurgical Transactions, and the case furnished by Dr. Latham, and published in the same paper, in which, on dissection, there were found two distinct ulcerations through the substance of the thyroid cartilage, which contained pus. Mr. Goodeve's case, published in the London Medical Journal, July, 1825, was probably of the same nature, as the patient's voice and respiration improved after the expulsion of a piece of bone from the glottis.

2. Abscesses in the vicinity of the windpipe, compressing that tube, are sometimes formed in the neck, under the fascia, and are discoverable by hardness, swelling, and pain on pressure, œdema, and inability to open the mouth widely; they are often accompanied with fever of a typhoid nature, which we have more than once considered as the primitive disease;* but as, by an incision, relief may occasionally be obtained, the treatment chiefly belongs to surgery. The usual situation of these abscesses, according to Mr. Porter, is behind the broad portion of the cricoid cartilage, where it presses on the rima glottidis. The progress of this disease is sometimes rapid; sometimes the abscess bursts behind the rima glottidis, and hectic ensues.

3. It will be necessary to recollect that aneurismal tumours have given rise to symptoms resembling those of laryngitis, of which there is an example in Mr. Lawrence's paper. We learn from that eminent surgeon, that a patient laboured under great difficulty of drawing air into the chest, coming on in fits, which Mr. Lawrence supposed

* These abscesses are frequently fatal, as in a case related by Dr. Tweedie, which occurred during convalescence from fever. Dr. Tweedie has also met with cases of symptomic laryngitis, both in continued and scarlet fever, which generally rapidly destroys life, by causing œdema of the glottis.—*Clinical Illustrations of Fever.*

might be relieved by bronchotomy, and therefore he desired that he might be sent for on the occurrence of a fit. After the patient's death, her disease was found to be an aneurism of the arteria innominata, situated between the first bone of the sternum, and pressing on the trachea. Mr. Wood knew an instance, in which tracheotomy was performed, which was attended with bursting of the aneurism into the trachea, and he refers to several such cases.

Pathology. — In several dissections which we have superintended, we have observed appearances corresponding with those described by Drs. Farre and Baillie, and Mr. Porter. Swelling, and other remains of inflammation of the tongue, velum, arch of the palate, and fauces, may occasionally be seen. The following appearances are always visible. The epiglottis thickened and erect, by which it ceases to protect the aperture of the windpipe; the mucous membrane of the glottis and larynx, as well as the epiglottis, thickened and vascular; underneath the mucous membrane, an infiltration of serum. This thickening of the mucous membrane and distension of the submucous tissue, from inflammation and effusion, bring the sides of the rima glottidis nearly into contact, and thus at length almost obliterate the passage.

Coagulable lymph has occasionally been found on the free surface of the mucous membrane. In the second case, related by Dr. Farre, in the third volume of the Medico-Chirurgical Transactions, coagulable lymph was effused from the inflamed surfaces about the glottis and epiglottis, and thus assisted in closing the rima. The tumefaction of the mucous membrane generally ceases at the junction of the larynx and trachea, but increased vascularity may sometimes be discovered in the trachea and bronchi.

The two phenomena which invariably characterize the anatomy of laryngitis, (the latter a consequence of the former,) are—1st, inflammation and some thickening of the mucous membrane; and 2dly, œdema underneath, which latter state, although it cannot be called peculiar to this affection, is a very unusual attendant upon any other disease of the mucous membrane.

[M. Cruveilhier divides laryngitis into two varieties, according as the diseased action is more conspicuous upon the surface of the mucous membrane of the larynx, or in the submucous cellular tissue, designating the former *mucous laryngitis*, the latter *submucous laryngitis*, which is the *œdema of the glottis* of others. In the consideration of this disease elsewhere, (*Practice of Medicine*, edit. cit. i. 227,) the writer has divided laryngitis into the *acute*, the *chronic*, and the *œdematous*.]

That laryngitis is an inflammatory affection, we have abundant proof. The fever which belongs to the disease is attended with increased heat of surface, and frequent and strong pulse. The blood is sizy. The parts affected are swelled and painful, and we may sometimes obtain a view of a portion of the affected organ in a state of intense inflammation. When the tongue is not much swelled, by depressing its root, by pushing the root downwards and forwards by means of a spatula, elevating at the same time the handle of the spatula, we can discover the epiglottis erect, florid, swelled, and rounded. One writer on the disease has well described the epiglottis as being enlarged, red, glossy, and nearly of the size and appearance of a plum (*Mr. Wilson*, vol. v. Medico-Chirurg. Transactions, p. 158): inflammation, thus denoted by swelling and glossy redness, is, doubtless, the state of the glottis as well as of the epiglottis.

Mere inflammation of the membrane will be productive of uneasiness and occasional difficulty of breathing, from spasmodic stricture. But effusion into the submucous tissue must render the difficulty of breathing permanent, and lead to asphyxia, when, from narrowing of the glottis, the supply of atmospheric air becomes insufficient to effect the removal of the venous character of the blood during its passage through the lungs, and when, consequently, those functions which depend upon the arterial properties of the blood being restored, and more especially the function of the brain, are interrupted.

In laryngitis, asphyxia may take place under a variety of circumstances. 1st. We have known asphyxia take place, in the course of the first night of the disease, from strangulation, the patient being found in the morning quite dead. 2dly. Asphyxia much more generally arises from gradual depravation of the circulating fluid. 3dly. Death may also take place after the obstruction has been removed by means of a surgical operation, as in the case of Mr. A. In such case, the brain, in consequence of the transmission to it of blood in a state of imperfect oxidation, receives a shock from which it never recovers, even when the lungs are again abundantly supplied with air. This is like the shock from submersion, which we have known to be fatal after the pulse and respiration had been restored. In the two latter cases, the patient dies from disease of the brain, and not from strangulation. Œdema productive of death may be the work of one night; yet, generally, the morbid process is prolonged for four or five days; the difficulty of breathing, at first often remitting, we apprehend must be referred partly to spasm, caused by inflammation of the membrane. In the progress of the disease, however, the dyspnœa becomes unremitting, which cannot be accounted for unless on the supposition of a permanent narrowing, the effect of œdema. If we had any certain means of ascertaining when the membrane is merely inflamed, and when it is œdematous as well as inflamed, much of the difficulty which attends the treatment of the disease would be removed.

Treatment.—But as we have no certain means of establishing the condition of the windpipe, we must be guided by the symptoms of the disease in deciding the question of bloodletting, which is one of the most difficult points in therapeutics. Although bloodletting may be expected to remove the inflammation of the mucous membrane, it cannot be expected to remove the effusion from the tissue beneath it: as well might we expect that bloodletting would remove phlegmon after matter is formed, as that it will remove laryngitis after œdema is established. It may prevent the further deposition of serum, and render it easier for the absorbents to act upon that which has been already effused; but more than this we are not to expect.

The practice of the physicians who attended the great American President during his last illness, was, we conceive, very unfairly decried by some of their professional brethren on this side of the Atlantic; and this is the more remarkable, as medical criticism was not so grossly vituperative thirty years ago as it is now. In a medical journal of 1800 we find the following specimen of gratuitous illiberality:—"Think of a man being, within the brief space of little more than twelve hours, deprived of eighty or perhaps ninety ounces of blood, after swallowing two moderate American doses of calomel, which were accompanied by an injection; then five grains of calomel, and five or six of emetic tartar; vapours of vinegar and water frequently inhaled; blisters applied to the extremities; a cataplasm of bran and vinegar to his throat, upon which a blister had been already fixed: is it surprising that, when thus treated, the afflicted general, after various ineffectual struggles for utterance, at length articulated a desire that he might be allowed to die without interruption! To have resisted the fatal operation of such Herculean remedies, one should imagine that this venerable old man ought at least to have retained the vigour of his earliest youth. A British physician may be deemed not competent to ascertain the propriety of transatlantic practice: the current of blood in the inhabitants of the new world may bear some proportion to the current of its rivers; in that case the medical treatment ought likewise to be conducted on a larger scale," &c. In answer to this rhapsody, in which the writer has tried to destroy the character of two respectable physicians, it may with truth be affirmed, that when these gentlemen pronounced the disease of which their illustrious patient died to be cynanche trachealis, they proved that they were not ignorant men. They showed that they were not ignorant of the seat and nature of the disease; they knew it to be seated in the upper part of the windpipe, and to be of an inflammatory nature. We venture to say that their critic would not have been nearer the mark. Perhaps there was not in Britain more than one individual, namely Monro, who was acquainted with the true nature of the disease of which General Washington died. The late Dr. Pitcairn, a physician in London, of deserved reputation and character, ten years after the death of General Washington, being attacked with the same disease, when no longer able to articulate, "wrote down with a pencil on a slip of paper that his complaint was to be considered as croup." Nay more; Dr. Pitcairn's case was the first which the late Dr. Baillie, then at the head of the medical profession in England, had ever witnessed; and that great physician, with his characteristic candour, admits that he was ignorant of the nature of the disease of which his friend Dr. Pitcairn was dying. Dr. Pitcairn, the day before he died, did not consider himself in danger, but thought that he was suffering under an attack of cynanche, such as he had often experienced, with a little more than its usual severity; and this, adds Dr. Baillie, was so much impressed on my mind, "that I did not even examine his throat, nor did he seem to wish it." Moreover, four hours before his death, when drowsiness was coming on, Dr. Baillie "thought him somewhat better." Hence it is probable that the best informed physicians in England, prior to the publication of Dr. Farre and Dr. Baillie's papers on cynanche laryngea, would have pronounced General Washington's case to be one of cynanche trachealis. This being admitted, the American physicians ought not to have been charged with ignorance, nor their practice so mercilessly impugned. What are the most approved remedies for croup? Bleeding, tartar-emetic, blisters, and, according to many, calomel: these were the remedies which General Washington's physicans prescribed, and which they administered, it must be admitted, with boldness. Whatever injury the patient sustained from the measures employed ought to be charged, not to the account of the intelligent physicians who attended him, but to the less perfect state of pathology at the end of the eighteenth century than at present.

General Washington died within twenty-four hours of the commencement of his illness; and we cannot deny that in this supposed case of croup, the remedies employed, however justifiable in the then state of medical information, probably shortened the general's life. If bleeding fails to subdue an inflammatory disease, it will be hurtful "by depressing the power by which the muscles act;" and on the vigorous action of the muscles which expand the chest, depends a continuance of that struggle by which the lungs are supplied with air sufficient for the arterialization of the blood.

We acquire a juster view of laryngitis by contrasting that disease with croup. They are both truly inflammatory diseases, but in that point alone do they resemble each other. Croup is a disease occurring before puberty, generally affecting, not merely the larynx, but the whole of the bronchial membrane, ending in an effusion of lymph on the free surface of the membrane, to be cured, probably, in ninety-nine cases of a hundred, by emetics and bleeding timely employed; and it is a disease in which a surgical operation will only add to the danger to which, in the second stage, the patient is exposed. Laryngitis, on the other hand, is a disease which rarely occurs before puberty; is confined to the upper extremity of the wind-pipe; ends in a serous effusion into the cellular tissue beneath the mucous membrane; will probably terminate unfavourably, in a great majority of cases, under any method of treatment; in which emetics aggravate the danger, and bleeding is often a doubtful remedy; and in which, when the patient is *in extremis*, bronchotomy will afford the only reasonable hope of safety.

Bloodletting has been successfully practised in this disease, as the reader may be convinced by several recorded cases: for example, by a case to be found in a paper on laryngitis, published by Dr. Beck, of New York, in the twelfth number of Dr. Beck's Journal. The case occurred in the person of Dr. Francis, one of the editors of the Journal, who, having for three days had soreness of the fauces and thirst, was attacked with pain, difficulty of breathing and swallowing, and a sense of strangulation, for which symptoms 152 ounces of blood were abstracted, as follows: On the 17th Nov., 1823, V. S. ad ℥xl.; evening, ℥xx. 18th Nov. ℥xvi.; evening, ℥xvi. 19th Nov. ℥xvi.;

evening, ℥xvi. 20th Nov. ℥xvi. 22d Nov. ℥xii.—Total, ℥clii. For three or four days after, the patient was still in a precarious condition, and required a repetition of the bloodletting. Other cases are published, in which the lancet was successfully employed: in one of these, to be found in the sixth volume of the Medico-Chirurgical Transactions, viz., that of Sir J. Macnamara Hayes, as reported by Dr. Roberts, of Bishop Stratford, we learn that the first bleeding "was attended with considerable relief," the second "with manifest advantage;" by the third, "his safety appeared to be ensured." In the case of a young woman who earned a pittance by gathering cockles on the strand at ebb-tide, and afterwards hawking them through the streets of Dublin, who, on the 13th of July, 1813, presented herself at the county of Dublin Infirmary, on the second day of laryngitis, pale, scarcely able to articulate or swallow: the effort producing a convulsion as when a crumb enters the wind-pipe, the voice sounding as if she were throttled,—inspiration being slower than natural and sibilous,—the following treatment proved successful. At noon, she was bled ad deliquium, which, by the way, had nearly proved fatal. The venesection was repeated twice in the course of the evening. On the following day, respiration was rendered difficult by the least exertion; hitherto unable to swallow. She was again bled, and a purgative enema and blister prescribed. Next day she began to expectorate yellow mucus, and could swallow fluids. On the 16th July, convalescent.

It is observable that the lividity of complexion which, especially in the more advanced stages of laryngitis, arises from imperfect arterialization of the blood, did not exist in any of these cases.

On the other hand, bloodletting has been unsuccessfully practised in laryngitis, not only in the case of General Washington, but also in many others. In the second attack of laryngitis, that to which Sir John Hayes fell a victim, he was three times bled from the arm on the second day of his illness; and the result of his case, and the other cases reported by Dr. Baillie, in which also bloodletting was practised, led Dr. Baillie to affirm that "venesection, even when employed strenuously and early, was of no real use." But the most remarkable instance of the inefficacy of bloodletting may be found in Dr. Armstrong's Practical Illustrations of Typhous Fever, p. 393. The loss of one hundred and sixty ounces of blood within six hours, gave temporary respite to the difficulty of breathing, yet was so far from arresting the inflammation, that death took place within twenty-four hours. As, then, there are cases in which bloodletting is salutary, and cases in which it is hurtful, let us try to ascertain when and to what extent that remedy ought to be practised; and let us be permitted to premise that cases will occur in which it may be difficult to come to a satisfactory conclusion with respect to bloodletting—in which the considerations for and against that remedy will be balanced, so as to make the most skilful and experienced physician pause. In such a dilemma, however, it will be well that the physician should not allow his doubts to transpire; as doubts which may be the result of an accurate weighing of indications against contra-indications, and which prove that he is a pathologist, will, perhaps, by the world and by his unreflecting brethren, be thought to proceed from inexperience and perplexity.

We conclude, first, that bloodletting will be more clearly indicated in youth than in age. It may be observed that the same means by which Sir John Hayes was relieved during his first attack, which took place in the meridian of life, failed fifteen years after:—and, secondly, that we may bleed with most hopes of success, when the symptoms of inflammatory fever are most evident. In Sir John Hayes, during the first attack, the face was swollen and flushed; the eyes were protruding and bloodshot; there was fulness about the neck, the muscles feeling very turgid, and the breast being suffused with a purplish colour; whereas, in the second attack, we find that his skin was not hot, nor his pulse more frequent than in health.

"At the beginning of the attack, it may be advisable," says Dr. Baillie, "to take as much blood at once as to produce fainting. We beg to submit to the reader, that blood in laryngitis is sometimes so imperfect a stimulus to the heart, that if the action of that organ is interrupted, it is not improbable that it will never be resumed. In certain conditions of the circulation in this disease, I have found bloodletting a very dangerous measure. I think it was fatal to a patient who came to the County of Dublin Infirmary about twenty years ago, when I was one of the physicians to that hospital. By my orders he was let blood, not till he fainted, but till he became pale and fainty; very shortly after the operation, which sensibly reduced his strength, he was seized, upon slightly exerting himself, with a paroxysm of difficult breathing, not more violent than many from which he had emerged, during the two or three previous days, and expired." In Dr. Beck's paper, already referred to, we learn that Dr. Hoffmann of the United States Navy was called to a patient in laryngitis whose countenance was anxious, flushed, and covered with sweat; eyes staring, and dyspnœa insufferable; that a vein was opened in each arm, which bled freely, and that death took place in a few minutes after. Mr. Porter, in the eleventh volume of the Medico-Chirurgical Transactions, after drawing a very lively and accurate portrait of laryngitis in a man about thirty years of age, who came to the Meath Hospital with his face pale and swollen, his lips livid, his mouth closed, his nostrils widely extended, his eyes protruded and starting from their sockets, but at the same time with the conjunctiva very white, and covered with a watery suffusion, and with an expression of indescribable anxiety; his pulse hurried, and his breathing very laborious, making two or three, or even more attempts at inspiration for one expiration, and his convulsive struggles for breath truly painful to behold, breathing with a hissing or whistling sound, while the utmost endeavour at speech was only an indistinct whisper;—tells us that he ordered from thirty to forty ounces of blood to be taken from both arms, and adds that in about two hours afterwards, when he returned to the hospital to perform bronchotomy, there was scarcely a pulse to be felt at the wrist; the extremities were cold; the patient lay on his back

almost insensible, and seemed sinking with amazing rapidity. Knowing the candour of the intelligent and skilful reporter of this case, we are not afraid to observe that this was a combination of symptoms in which bloodletting was not likely to improve the condition of the patient, for whose sufferings the proper remedy was the knife, which was afterwards successfully employed. Indeed, Mr. Porter, in his valuable remarks on the case, has affirmed that it presents a strong illustration of the inefficacy, in laryngitis, of bleeding, blisters, and the various internal means usually resorted to for the purpose of subduing inflammation. We conclude, that although we may bleed in certain states of the disease so as to influence the pulse, it would be unsafe under any circumstances to bleed usque ad deliquium.

The question of bleeding may with most safety be determined by the condition of the circulating fluid. We may, with comparative safety, bleed while the complexion is good, or, in other words, so long as the quantity of atmospheric air admitted into the lungs is sufficient to produce that chemical change by which venous blood, in passing from the right ventricle to the left auricle, is converted into arterial; but when the alteration in the appearance of the patient takes place remarked in the advanced stages of the disease, which indicates that the blood is no longer arterialized in its passage through the lungs; when the face and lips, especially the latter, become livid, the expression anxious, the eyes protruded and watery, and when these appearances are established permanently, we may conclude that the stricture of the glottis is of a nature not to be relieved by bloodletting, and if so, that the patient will be injured thereby.

In the early stages of laryngitis, would not the application of leeches to the palate and tonsils be deserving of a trial? This question the reader will be better able to answer after he shall have read a short but valuable paper by Surgeon General Crampton, in the third volume of the Dublin Hospital Reports, on the application of leeches to internal surfaces. Mr. Crampton informs us, that in no instance in which leeches have been applied to the tonsils within the first twelve hours of the attack of inflammation, has the disease proceeded to suppuration.

We would bleed the patient freely during the first twenty-four hours; we should be disposed to do more—so long as the complexion of the patient is good, we would have recourse to venesection, keeping a finger on the artery while the blood flows, and closing the orifice when the pulse is reduced: we would have leeches applied, or blood removed from the nucha by cupping; and should be disposed to bleed again, or even a third time, so as to abstract forty or fifty ounces of blood, and at the same time let the patient have a powder containing two or three grains of calomel, three or four of pulvis Jacobi veri, and one-half or one-third of a grain of opium, every third or fourth hour, till the gums become affected. This we prefer to an exhibition of tartar-emetic, not wishing to expose the patient to the danger of vomiting, which is productive of a frightful struggle in laryngitis. Blistering the neck is of very questionable efficacy, and by the inflammation, stiffness, and soreness which it occasions, adds much to the sufferings of the patient, and, when bronchotomy becomes necessary, to the inconveniences which attend that operation. If the physician reposes much confidence in the antiphlogistic power of a blister, let it be deferred till bleeding has been carried as far as is expedient, and then let it be applied to the upper part of the sternum.

"From bleeding and opiates," says Dr. Baillie, "if no substantial advantage is produced in thirty hours, it might be advisable to perform the operation of bronchotomy at the upper part of the trachea, just under the thyroid gland." We apprehend, however, that a consideration of the mere duration of the disease will lead us astray; thirty hours may be too long to wait, or it may be too short. If the circumstances of the patient, especially the condition of the circulating fluid, be such as to contra-indicate bleeding, and to show that asphyxia is imminent, it may be improper to put off the operation for thirty minutes. If the complexion is good, if asphyxia is not threatened, the operation may be delayed for thirty days.

In Dr. Baillie's second case already referred to, it is stated, "in the night time, the patient becoming much worse, Mr. Tegart, who scarcely ever left him night or day, went for Mr. Home and Mr. Wilson to perform the operation of bronchotomy. Mr. Wilson was out of town on professional business, but Mr. Home came about four in the morning. The patient, however, was beginning to sink, so that no advantage from an operation was now to be expected." It is, indeed, probable that bronchotomy would not have saved the patient; but as that operation in an adult can be performed without difficulty, and as there are instances of its having been successful even when the brain was oppressed, which is the most alarming symptom in this disease, we humbly think that no patient who is not in the article of death ought to be deprived of the chance of escape which it affords. The patient operated upon by Mr. Goodeve, surgeon to the Clifton Dispensary, was quite insensible when the operation was performed; "no pulse could be found at the wrist, his face was suffused with blood and his lips livid, and it was hard to say whether he breathed or not," and yet he recovered.

There can be little doubt but that in most cases the aperture ought to be made between the thyroid and cricoid cartilages, but in this matter the surgeon must be the arbiter.* The operation has

* On this subject consult Mr. Lawrence's paper in the sixth vol. of the Medico-Chirurgical Transactions.

The writer of this article many years ago recommended the introduction of a trocar and cannula, without previous incision. This operation is justly condemned by Mr. Wood in his valuable paper published in the seventeenth vol. of the Medico-Chirurgical Transactions. Mr. Wood observes: "Dr. Cheyne has advocated an operation equally reprehensible with that of Dessault, who recommended the introduction of an elastic tube through the nostril into the trachea, *that of introducing into the trachea a trocar and canula without previous incision.* The reflection that the canula must irritate by being moved up and down with the larynx, which does not move in association with the skin, combined with the danger of wounding a large blood-vessel irregular in its course, the œsophagus and contiguous important parts, and the depth it may be necessary to penetrate in consequence of the unusual depth of the trachea from the surface, ought to preclude this use of the trocar," &c. This quotation is introduced as an *amende* for the inconsideration that led to the proposal of an operation which is so objectionable.

often proved perfectly successful, and a canula has been worn for a long time without much inconvenience. Thus the patient operated upon by Mr. Goodeve wore a tube for more than six months; he was then able to lay it aside, and his voice was quite restored. In the fourth volume of the Dublin Hospital Reports, we learn from Mr. White that one of his patients was wearing a tube without being prevented from working at his trade, which was that of a cabinet-maker, two years after the operation; the sides of the opening, which was of an oval shape, and one inch in depth to the trachea, being perfectly healed, smooth, and covered with a thin cuticle. But the most remarkable proof of the relief which the canula is capable of affording, is that which is supplied by the case of Mr. Price of Portsmouth; we learn in the twenty-ninth number of the Medico-Chirurgical Review, in which journal there is much valuable information to be found on laryngitis, that Mr. Price had been breathing for about fifteen years through a canula.

Laryngitis sometimes is more of a chronic than acute affection, in which case the affected organ probably undergoes a considerable change of structure; in the case in Mr. Lawrence's paper, which we have already alluded to, which continued for nearly four months, the mucous membrane had assumed a thick and puckered condition, and had partially thrown out coagulable lymph of a stringy and fimbriated texture, which obliterated the ventricles of the larynx. In one of our cases which had lasted four months, the membrane lining the glottis, and arytenoid cartilage, was like a thin layer of flexible cartilage. In chronic laryngitis, *mutatis mutandis*, the same principles of treatment are applicable as in the acute species. Bronchotomy may be necessary to prevent that fatal exhaustion arising from continued disturbance of the respiratory function, as it was in the case related by Dr. M. Hall in the tenth volume of the Medico-Chirurgical Transactions; but medical means alone will often prove sufficient for the removal of the inflammation, if it be unaccompanied with ulceration. The remedies chiefly to be relied on in chronic succeeding acute laryngitis, are, change of air—this remedy we again specify, even at the risk of being thought to harp a little too much upon one string; — the establishment of a discharge from both sides of the larynx by means of small caustic issues; and mild mercurials, with the infusum sarsaparillæ compositum of the Dublin pharmacopœia.

J. Cheyne.

[*Chronic Laryngitis* has received more attention of late years than formerly, and will, therefore, require further consideration. This term has been employed synonymously with *Laryngeal phthisis*, *Phthisis laryngea*; whilst laryngeal phthisis itself has been employed by MM. Trousseau and Belloq, so as to comprise "any chronic alteration of the larynx, which may bring on consumption or death in any way." It has been used, indeed, to include all chronic diseases of the larynx. In this place, the epithet "chronic" is employed in regard to laryngitis, in the same manner in which it is applied to other inflammations of mucous membranes:—to signify inflammation of the lining membrane of the larynx, or of the subjacent parts, the duration of which is long, or whose symptoms proceed slowly.

Diagnosis.—The commencement of chronic inflammation of the various structures composing the larynx is often extremely insidious, and its progress so tardy, that much, and often irreparable mischief is accomplished before any alarm is taken by the patient, and he applies for medical assistance. Pain is felt in the larynx, but its precise situation may vary; at times, it extends over the larynx; but, at others, is restricted to a small space, and generally to the region of the thyroid cartilage. Commonly, a kind of tickling sensation exists, which provokes coughing. The pain, too, is exasperated by coughing, speaking, and deglutition, especially when ulcerations exist, and they are situate above the ventricles of the larynx. The breathing of cold air, and pressure upon the larynx likewise augment it. The voice is almost always changed, being hoarse, and, at times, so much enfeebled, as to be inaudible. The aphonia may supervene suddenly or gradually, and ultimately be complete. Cough is a constant concomitant, and when the mucous membrane is much swollen, it becomes hoarse and even croupy. In the first instance it is dry, but subsequently it is accompanied with the expectoration of mucus, mixed occasionally with pus or blood. At other times, a membraniform matter is expectorated for months; and at others a considerable quantity of false membrane is thrown off, after which the patient rapidly recovers. Occasionally, portions of cartilage are mixed with the mucous or bloody sputa, and in such cases, there is always accompanying hectic. Chronic laryngitis has, indeed, been divided into two heads;—the first comprising that which affects the mucous membrane and the submucous tissue; and the second, that which implicates the cartilages; the latter—it has been conceived—having perhaps the best claim to the name *phthisis laryngea*, from the incurable nature of the affection, and the hectic and emaciation, which invariably accompany its latter stages.

When chronic laryngitis is slight, and there is not much narrowness, the difficulty of breathing may not be great; but if it be attended with much tumefaction of the lining membrane, the dyspnœa is considerable, and the sound, on inspiration, sonorous and peculiar. It is evidently, too, augmented by paroxysms. The air of inspiration likewise gives rise to a snoring (*ronflement*) or whistling, (*sifflement*,) which may be continuous, or recur in paroxysms. These local symptoms may be so slight, that the general health does not suffer to any great degree. Commonly, however, more or less sympathetic febrile disorder is apparent, under which nutrition is impaired, and atrophy supervenes. The disease now merits the term *Laryngeal Phthisis*, which is, however, in the immense majority of cases, connected with the presence of pulmonary tubercles.

Chronic laryngitis may be primary, or it may succeed to acute laryngitis, and when apparently terminating in health, it is readily reproduced by exposure to cold, errors in diet, &c. &c. Its duration varies from a few months to several years.

When the fauces are inspected, but little evidence of disease may be perceptible; at other

times, however, the mucous membrane is injected, and the follicles are so large as to resemble split peas. Whether this enlargement of the follicles be the cause or effect, may admit of a question. The enlarged follicles probably exist lower down, where they cannot be inspected. This form of laryngitis is the one often known under the name "*Clergymen's sore throat.*"

Chronic laryngitis may terminate in health; but it is more likely to end fatally; and this may occur in different modes,—either by the lungs becoming implicated, or by the extent of the laryngeal lesions themselves, which may excite severe irritative fever, or interfere with the entrance of air into the lungs, and thus induce asphyxia. In almost all cases of phthisis laryngea, the disease is complicated with pulmonary tubercle. Dr. Stokes, indeed, asserts, (*On Diseases of the Chest*, Amer. edit., Philad. 1844,) that after ten years of hospital and private practice, he never saw a case presenting the symptoms of laryngeal cough, purulent or mucopurulent expectoration, semi-stridulous breathing, hoarseness, or aphouia, hectic, and emaciation, in which the patient did not die with cavities in his lungs. In some, the laryngeal affection seemed to be primary; but, in the great majority, symptoms of pulmonary disease existed previous to its appearance. Such, also, is the result of the writer's observation.

In many cases of pulmonary phthisis, — sore throat, hoarseness, or aphonia, with cough, occur; but the case is different, when the laryngeal symptoms have been primary.

Causes.—The same causes, that give rise to acute laryngitis, may induce the chronic form also. It may be caused, like the acute, by the inspiration of acrid substances, or by extraneous bodies received into the larynx. The habitual and intemperate use of ardent spirits has likewise been esteemed a cause, as well as the effects of mercury. These act either as predisposing or exciting causes. It is often the result of phthisis pulmonalis; whilst, on the other hand, the pulmonary irritation, induced by it, may occasion the development, and augment the course of tuberculosis of the lungs in those who are predisposed to pulmonary consumption. The coexistence of ulceration of the lungs, and of suppurated pulmonary tubercles, has often been proved. In one-fourth of the cases of phthisis, ulceration of the larynx has been observed; in one-sixth, ulceration of the epiglottis; and ulceration of the trachea was met with by M. Louis, more frequently than either of the other lesions. (On *Phthisis*, 2d edit., translated by Dr. Walshe —Sydenham Society edit. Lond. 1844.) It is probable, however, that the idiopathic chronic laryngitis rarely produces the symptoms of phthisis; but the two diseases are frequent concomitants.

Amongst the exciting causes are mentioned—prolonged action of the vocal organs; hence the disease is said to be frequent among actors, singers, lawyers, preachers, &c. It has already been remarked, that it is so common among the last as to have received the name of the *clergymen's sore throat;* yet why it should prevail among them more than among lawyers, professors, &c., who use their vocal organs more, is not so clear. It has, indeed, been suggested, by Professor Chapman of Philadelphia, that clergymen, as a class, are of feebler constitutions, which circumstance may have originally led them to embrace their avocation; and, hence, that they are more liable to such derangements than more healthy individuals; but this does not seem sufficient to account for the difference. Another explanation has been offered by Dr. Stokes—(*Op. cit.*) that the clergyman begins to exercise his vocal organs at a much earlier period than the lawyer, for example. The young clergyman, often of a feeble and nervous constitution, and acting under conscientious motives, to the neglect of bodily health, not only reads the service, and preaches once or twice, or even more frequently in the week, but is exposed to night air and the inclemency of the weather. He is compelled to do so, while both the larynx and constitution of the lawyer have generally full time for maturity, before he need employ the one or expend the other in the duties of his profession.

Syphilis would appear to be a frequent cause of chronic laryngitis, and especially of the ulcerative form,—the ulcers extending, at times, from the throat by continuity of surface.

As to age, the disease has certainly been observed most commonly between twenty and forty; but, as to sex, discrepancy of sentiment exists;—some, as Ryland, (*On the Diseases and Injuries of the Larynx and Trachea*, Amer. Med. Lib. edit. Philad. 1838,) affirming, that the number of females, attacked by it, is infinitely greater than that of males; others, as Andral, (*Cours de Pathologie Interne*,) that males are more frequently affected than females.

Pathological Characters.—Chronic inflammation induces the same changes in the laryngeal mucous membrane as in other membranes of the class; for example, redness, increased thickness, and alteration of consistency, over a greater or less extent of surface. Occasionally, too, vegetations of considerable size, and white and hard granulations are perceptible. Pus, too, is generally found covering its surface. The mucous follicles, both of the lining membrane of the pharynx and larynx, are frequently enlarged, especially in that form of the disease to which clergymen are subject, and they seem filled with a yellowish matter. Ulcerations are likewise very common, so as even to destroy the vocal cords. The submucous cellular tissue is often infiltrated by a thin fluid; and, at times, collections of pus exist in it; at others, it is indurated, and tubercles are found in different stages of development. The intrinsic muscles of the larynx have been found much reduced in size, softened and occasionally destroyed. At other times, they have been hypertrophied. The epiglottis may be thickened, ulcerated, carious, and even completely destroyed; yet the patient may have been able to swallow to the last. Of the cartilages of the larynx, the cricoid and the arytenoid are most frequently diseased—the thyroid least so. Occasionally, they are ossified, or ossific points are deposited on the mucous membrane. In broken down constitutions, in which large quantities of mercury have been used, it has been remarked, by Drs. Graves and Stokes, that chronic laryngitis is very apt to terminate in ulceration of the cartilages.

Treatment.—In the treatment of chronic laryngitis, at all stages, rest of the vocal organs is

indispensable; but it is difficult to have it rigorously enforced. In the early periods, bloodletting from the arm is sometimes demanded, and in almost every case, it will be advisable to apply cups to the nape of the neck, or top of the chest; or, what is better, leeches freely over the seat of the disease. Emollient fomentations and poultices, likewise afford relief, but they have been objected to—probably altogether on hypothetical considerations—under the idea that they solicit an increased flow of blood towards the throat, and thus aggravate the disease. Revellents are, certainly, important remedies. A blister may be applied to the top of the sternum, or over the trachea, and as soon as it heals, another should be applied, so as to keep up an intermittent, which is preferable to a permanent, irritation. Hence blisters, thus employed, are better than setons; and the ointment of the tartrate of antimony and potassa, or the croton oil, is, perhaps, preferable to either.

With the view of procuring rest, opium and its preparations may be given. They are useful, likewise, in allaying cough. The salts of morphia may also be employed endermically, and advantage has been derived from frictions over the larynx, with the extract of belladonna.

Where the affection of the larynx has lost its inflammatory characters, and any of its terminations remain, topical remedies may be employed. These have, indeed, been regarded by MM. Trousseau and Belloq (*Practical Treatise on Laryngeal Phthisis*, translated by Dr. Warder, Amer. Med. Lib. Edit. Philad. 1838) as the most efficacious of all. They may be made to come into immediate contact with the diseased surface itself. At an early period of the disease, inhalations of the steam of warm water may be employed with advantage, but subsequently more excitant applications are needed, to induce a new action in the diseased surface. Inhalations, however, are liable to the inconvenience, that they cannot be restricted to the larynx; and, consequently, no agents are administered, in this manner, in cases of chronic laryngitis, except such as do not over-excite the mucous membrane of the lungs. The vapour of hot water, to which one of the essential oils has been added, may be used in the way of inhalation, with safety and occasional benefit. Various forms of apparatus have been devised for this purpose; but MM. Trousseau and Belloq frankly confess, that a simple teapot is as well adapted to the purpose as the most complicated machines. In this way, chlorine, creasote, and iodine, may be inhaled under the circumstances laid down under Tubercular Phthisis.

Topical remedies in solution are more to be relied on. Of these, nitrate of silver, corrosive sublimate, sulphate of copper, nitrate of mercury, and Lugol's caustic solution of iodine, (see the writer's *New Remedies*, 4th edition, Philad. 1843,) have been employed; but the nitrate of silver is to be preferred, on account of its rapidity of action and harmlessness. It may be used in the proportion of ten or fifteen grains to the ounce of water, and it has been prescribed as strong as one part of the nitrate to two parts of water. Various plans have been adopted for applying it. The author uses a mop of rag at the extremity of a piece of whalebone. Others attach a piece of sponge to the end of a quill, dip it in the solution, and having slightly squeezed it to prevent the fluid from dropping, they touch the posterior fauces; raise the outer extremity of the quill so that the sponge may touch the epiglottis and superior part of the larynx, and draw it gently out in this manner. Thus, the solution is made to come into immediate contact with the inflamed surface. By others, it has been advised to take up a drop of the strong solution on the bent extremity of a piece of firmly rolled paper, or whalebone, and to cause this to touch the lining membrane of the larynx. It has been suggested, that the solution may be thrown, in the form of a shower, into the larynx, from a small silver syringe, like Anel's; but the plans, already recommended, have the merit of being more easy of application.

A plan—before mentioned—proposed by Mr. Cusack, of Dublin, has been regarded by a competent witness, Dr. Stokes, (*Op. cit.*) as the best of all. A brush of lint, of the requisite size, is sewed on the end of the finger of a glove, which is then drawn on the index finger of the right hand. The patient is made to gargle with warm water, and the lint being dipped in the solution, can be readily applied to the larynx.

When the disease is dependent upon any syphilitic *vice*, it may be necessary to administer mercury, or some other revulsive agent—iodine, for example. When mercury is pushed so as to affect the mouth, it sometimes breaks in upon the morbid chain where no *vice* is suspected or present. It should be given, under such circumstances, so as to exert its ordinary influence slightly on the mouth. When, however, pulmonary tubercles are coexistent, care must be taken in the administration of this potent remedy, as the dyscrasy, induced by it, is apt to cause their development. Where the disease is dependent upon the use of mercury, it should, of course, be carefully abstained from, and an appropriate treatment, in which rest and the free use of iodine are combined, should be prescribed.

In many cases, the spasmodic exacerbations are very severe and distressing: they may be assuaged by opiates, or by the application of the *emplastrum belladonnæ* or *emplastrum opii*.

Lastly,—a question may arise as to the necessity for the operation of tracheotomy. Although frequently demanded in acute laryngitis, and not to be postponed, it is rarely necessary in cases of chronic laryngitis; but should symptoms, similar to those of acute laryngitis, which demand the operation, arise, it must be unhesitatingly performed. It is probable, however, that in such a case, the operation could be of but transient benefit; so much disorganization must have occurred as to render ultimate recovery almost wholly, if not wholly hopeless. Robley Dunglison.]

LATENT DISEASES.—It is a fact familiar to every physician practically conversant with the features of disease, that many disorders, even those of which the presence is commonly indicated by well-marked symptoms, will in particular cases present, throughout the whole or a great part of their course, a material deficiency or total absence of their usual external characters; and that on this account they are frequently on the one hand

confounded with other diseases, on the other entirely concealed from observation.

Considering the obvious importance of this subject in a practical point of view—especially, it may be added, to those just entering on their profession,—it scarcely seems to have hitherto received from pathological authors in modern times that systematic attention to which it has an undoubted claim. In ordinary practice every observant physician is subject to be taken at unawares by the sudden transformation or sudden development of the symptoms of diseased action, long latent in the system, and secretly advanced beyond the reach of a remedy. And in the practice of one particular branch of his art, that of medical jurisprudence, nothing is more common than to find his opinion and conduct embarrassed by sudden death arising in the like circumstances —by the discovery of appearances in the dead body adequate apparently to account for death, yet unconnected with any traces of the existence of corresponding disease during life. It would be an object of some consequence then to investigate the subject of latent diseases systematically in both of its relations now mentioned, — to present a classification of the several diseases which are apt to assume a latent course, a sketch of the circumstances in which they are liable to occur in this form, and an exposition of the phenomena in the living body which may lead to a suspicion or conviction of their presence, as well as a statement of the evidence by which, in the case of the sudden extinction of life, we may determine from the appearances in the dead body, taken along with other collateral considerations, what has been the real cause of death.

The great extent of the subject, combined with other circumstances, prevents us from undertaking at present what must be to the generality of the profession the more important and interesting department of this inquiry, — that, namely, which concerns latent diseases in their relations to ordinary practice. In undertaking to give some account of their medico-legal relations, it is almost unnecessary to observe, that the writer was first led to review the subject in consequence of its having been often brought forcibly under his attention during a period when he was frequently consulted in medico-legal cases, and that the hints which follow are chiefly derived from a consideration of what then appeared defective in our knowledge.

The importance of latent diseases in respect to medical jurisprudence depends on the consideration that sudden death, as one of their results, often leads to a judicial inquiry into its cause, even where no suspicions exist in regard to its manner; that sudden death from latent diseases frequently occurs where collateral circumstances lead to a suspicion of violence; that they are apt to prove suddenly fatal from the operation of slight violence or of circumstances incidental to violence, such as anger, struggling, or the like; and that the appearances they leave in the dead body may exist in the same organs, or even also present the same characters, with the appearances occasioned by death from violence of various kinds. On all these accounts latent diseases come frequently before the physician in his medico-legal capacity, and may give rise to medico-legal questions of much nicety. The remarks which follow are intended to exemplify what is now stated, and to supply as far as possible the means of investigating the cases here alluded to. These objects will be best attained by considering, first, what diseases are apt to put on a latent character and occasion sudden death; and next, by what means it may be proved in special cases that they have really been the occasion of death.

There are many diseases which may exist for a long time, and even advance so far as to cause decided injury to organs important to life, without seriously incommoding the patient and without occasioning death. Nay, there are many diseases, among those usually marked by prominent symptoms throughout, which may go on for a length of time and occasion most extensive organic derangement, without attracting the attention of the patient or his friends by any external sign, without producing ill health of any kind, and still more without being the occasion of death. In many such instances indeed the symptoms proper to the disease are incidentally developed after a time, and then follow their usual course to a favourable or unfavourable termination. But often, too, no such development takes place, and death may ensue suddenly, nay instantaneously, either from the disease attaining a certain point incompatible with the further continuance of life, or from some circumstances connected with it of which the operation cannot be satisfactorily traced: and, which is perhaps still more common, death may be occasioned by some other unconnected cause, and the first hint of the existence of latent disease is the discovery in the dead body of extensive alterations of structure, such as might be regarded, were it not for such occurrences, wholly inconsistent with the discharge of the most important vital functions.

It would not be easy to give a complete catalogue of the diseases which may thus run a latent course. Probably, indeed, such a catalogue would be found to comprise all or nearly all the diseases which give rise to important derangements of structure in the chief internal organs of the body. But it may be of use to indicate those which are most apt to assume the latent form, because such alone appear of material consequence to the practitioner.

Among the diseases of the head, those which are chiefly apt to present themselves in a latent form are sanguineous apoplexy, inflammation of the cerebral membranes, and inflammation of the substance of the brain.

Sanguineous Apoplexy often runs its course so rapidly, although with distinct symptoms, that in reference to practical questions of a medico-legal nature, it presents all the peculiarities and all the importance of a truly latent disease; but it would be out of place to treat of it in that respect at present. In numerous instances, however, sanguineous effusion within the head may take place without occasioning the usual apoplectic symptoms, and the individual may live so long that complete recovery takes place by organization and absorption of the clot, or he may be cut off at an earlier period by some other cause. The proof of this is, that clots both old and recent are

not uncommonly found within the head, and more especially in the substance of the brain, where the individual was cut off by a wholly different disease, and where there was sufficient evidence that symptoms of an apoplectic nature never had presented themselves. In a case therefore where the manner of death is doubtful, and a medico-legal examination becomes necessary, it is not enough to account for death that a clot be found in the brain, particularly if it be plainly of some standing. Further evidence may be necessary to connect this appearance with the death of the individual.

It is seldom that **inflammation of the membranes of the brain** assumes a latent form throughout its whole course, yet in some instances the symptoms are extremely obscure for a time, so that the nature of the disease is at first misunderstood; and occasionally it has happened that no well-marked indications of disease are developed till a short time before death, and even then the symptoms are merely such as may terminate organic affections of the head in general,—namely, stupor, coma, and convulsions. One distinct case in point has been related by the writer elsewhere, that of a middle-aged female, who died suddenly from chronic and circumscribed inflammation of the membranes of the brain. In this case the membranes and also a part of the brain were covered with pus, the corresponding portions of the temporal and occipal bones were denuded and similarly lined with purulent matter, and a portion had even escaped into the cavity of the ear. This affection had commenced in the bones at least a twelvemonth before, because the patient had been affected for that time with a purulent discharge from the ear. There can be no doubt, too, that the inflammation of the membranes which was the immediate occasion of death, and was produced by the disease of the bone being propagated inwards, must have existed for a considerable length of time, yet no symptom of its existence was detected till she was suddenly seized with acute pain in the head, and then with stupor and convulsions, under which symptoms she died within twenty hours. A case somewhat like this, but where the meningeal inflammation was more extensive, has been related by Dr. Powell, in the fifth volume of the Transactions of the London College of Physicians.

But even meningitis of a more diffused character, and commencing without previous disease in adjacent parts, may likewise put on this singular form, as will appear from the following remarkable case related by Dr. Crispin, in the "Annali Univ. di Medicina." A stout healthy young woman complained for two days of slight headach, without any other indication either of disorder within the head or of any other affection, and was then quite suddenly seized with loss of speech, complete coma, and febrile reaction, under which symptoms she died in the course of the ensuing night. On dissection, there was found suppuration of the arachnoid membrane, while all the other parts of the brain and its membranes, as well as all the other organs of the body, were in the healthy state. (Prospetto Clinico, in Annali, &c. Maggio, 1833.)

It is not improbable that to the same head of latent chronic meningitis should be referred those remarkable cases where extensive serous effusion over the brain or within the ventricles has been found after death in persons either dying suddenly without any pre-existing symptoms, or expiring slowly under symptoms wholly unconnected with the morbid appearances. Dr. Abercrombie relates an instance of the latter description from the experience of Professor Turner of Edinburgh, where serosity was extensively effused under the membranes of the brain as well as in the ventricles, and where the patient presented no signs of an affection of the head, but appeared to be gradually worn out by some chronic disorder of the pelvic viscera, which, however, were found to be healthy. (On Diseases of the Brain, p. 214, third edition.) The same author mentions two similar cases from the works of Morgagni and Heberden, in one of which the effused fluid amounted to eight ounces, without any corresponding symptom during life. (Ibid. p. 143.) Perhaps the following extraordinary instance may be classed with the foregoing. But whether it be viewed as an example of latent meningitis or not, it is well worthy of notice as an illustration of the great difficulty which the occasional occurrence of cases of an allied nature may introduce into medico-legal inquiries, and of the importance of the whole subject of latent diseases. A man of the name of Kennoway was tried in Edinburgh, in 1825, for parricide, under the following circumstances. His sister left him in a state of furious intoxication, quarrelling and struggling with his father, an old man of seventy, of passionate disposition, but enjoying good health. On his quitting the house she returned—not above seven minutes after she left them together—when she found the old man lying dead on his back, with the marks of two blows on the nose and forehead, not particularly severe. On dissection there was found no fracture of the bone, no extravasation beneath it, no laceration of the brain, but an effusion of half a pint of reddish serum in the ventricles, and also towards a pint of serum in the cavity of the pleura on each side of the chest. This case presented several other features of interest foreign to the object for which it is now referred to. At present it may be observed, that the medical gentlemen who conducted the examination ascribed death to the effusion in the ventricles, and the effusion to the blow. But it is quite clear that the latter statement is untenable—that the effusion must have taken a much longer time to collect than seven minutes, and the most rational view of the case seems to be, that the effusion was the result of latent chronic meningitis.

Among diseases which leave their traces within the head, none is more subject to assume a latent form than **inflammation of the cerebral substance.** From numerous cases which have been related by various authors, it follows that in its chronic form inflammation of the cerebral tissue—that form of disease which is now familiarly known to terminate in suppuration or in softening of the brain—is seldom marked at the beginning by characteristic symptoms; that it often advances to a great height with scarcely any apparent

signs of its existence, or even of ill health of any kind, till only a few days before death; and that not unfrequently it even proves suddenly or almost instantaneously fatal during a state of apparently perfect health. The following illustrations have been already given by the writer in another work, but may be here briefly recapitulated. In a case related by M. Louis, where death slowly terminated an attack of diseased heart, and where no symptoms of an affection of the head occurred at any time, an extensive softening was found in the thalamus and corpus striatum of one side. (Recherches Anat. Pathol. 313.) In another, mentioned by Lancisi, where slight occasional fits of lethargy succeeded an attack of apoplexy, death occurred suddenly more than a year afterwards, and an extensive suppuration of the brain was found surrounding a clot. (De Mort. Subit. p. 12.) In another, which occurred to the writer himself, and which from its circumstances led to a medico-legal investigation, a twelve hours' illness consisting of coma and convulsions preceded death, and there was found superficial circumscribed ulceration of the anterior lobe of the brain. In another, which likewise occurred in the practice of the writer, a similar superficial softening and ulceration of the surface of the brain over the left orbit was found, although the patient had been affected with coma for an hour and a half only, and had previously enjoyed good health. (Treatise on Poisons, 574.) Lastly, in a remarkable instance described in the London Medical Repository, where death took place instantaneously, without any precursory illness at all, while the individual, a sailor, was pulling an oar, there was discovered on dissection in the central parts of the brain an extensive softening and suppuration, which in the form of an abscess had made its way to the outer surface of the organ. (Vol. ii. 318. N. S.)

Diseases of the chest run an obscure or completely latent course much more frequently than diseases of the head, and among these the most remarkable are pleurisy, peripneumony, and organic diseases of the heart.

As to **pleurisy**, it is remarked that sometimes the early, and at other times the middle stage is latent. There are either no symptoms at all, or they are so slight as to escape notice; or, though obvious at first, they disappear afterwards, and seem to be succeeded by convalescence or even complete re-establishment of health. Lymph and serum, however, or sometimes purulent matter, have in the mean time been effused into the cavity of the chest, and the effusion goes on silently increasing till one side of the chest is completely filled, and the corresponding lung compressed and unserviceable. And at length, occasionally after a long interval, the individual is seized with laborious breathing, and dies in a few days or hours, or even instantaneously.

An instance where the interval of obvious illness lasted for a few days, occurred in Edinburgh in January, 1826, and led to a medico-legal investigation, in consequence of the patient's friends having neglected to obtain medical advice, and refused information to the neighbours who afterwards inquired into the case. The symptoms were difficult breathing, cough and pain of chest, slight at first and severe only for a short time before death, which took place in the course of the third day. On dissection one side of the chest was found filled with serous fluid, together with evident collateral signs of the effusion having been of old standing; and it was ascertained that several months before, recovery had to all appearance been attained from a severe attack of pleurisy and consequent hydrothorax. A more remarkable instance, where the pectoral symptoms subsisted for a few hours only, is related in Corvisart's Journal. In this case the patient, who was convalescent from an attack of simple fever, was suddenly taken ill with great oppression in the chest, and died within twenty-four hours, and the left side of the chest was found filled with five pints of serum, and the heart covered with a net-work of lymph, evidently showing the existence of an old pleuro-pericarditis. (Journ. de Méd. xxviii. 100.) But the most common cases of the kind under consideration are where the disease is concealed throughout its whole progress, or becomes so after a time, and death takes place instantaneously. Of such a course the following are apt illustrations. A girl in the wards of the Edinburgh Infirmary, under the writer's care, while convalescent apparently from nothing more than a mild attack of simple fever with insignificant pectoral symptoms, suddenly dropped down dead while sitting by the fire and laughing with her fellow-convalescents, and on dissection there was found a copious effusion of serum and lymph into the right side of the chest, with complete condensation of the right lung. An elderly man under the care of another physician of the same hospital was admitted in the agony of suffocation from hydrothorax consequent on pleurisy, but recovered apparently, and in six weeks was considered nearly fit for being discharged. But one morning, while in the act of making his bed and exerting himself with unusual force, he was seen to drop down on the floor, and the nurse running up to him, found him quite dead. Five pints of serum were found in the right side of the chest, and no other morbid appearance could be discovered.

Peripneumony is similarly circumstanced. It is a matter of daily observation, as Laennec has pointed out, that very great differences prevail in different cases in the amount of organic alteration which takes place in ordinary cases of inflammation of the lungs, before death ensues from oppression of the breathing. It follows that, even in acute inflammation, the function of the lungs may be much interfered with by the inflammatory process, without necessarily endangering life. It is not surprising, then, that where the local inflammation is chronic, and the constitutional derangement slight or wholly absent, very extensive ravages may be committed by the disease without its giving any local sign of its presence. Many cases might be quoted in illustration of the fact that chronic peripneumony may advance till it completely obstructs a whole lung, without any sign of oppression of the functions of the lungs; and in such cases death may occur suddenly, without any fresh cause appearing to act, or it may be occasioned by some other disease or agent of a different kind, such as violence. The following are examples.

A man, who, with the exception of a slight cough, enjoyed excellent health, died suddenly one night, while making a slight effort; and one lung was found wholly disorganized and formed into a sac of purulent matter, which had burst into the general cavity of the pleura. (Dict. des Sc. Méd. art. *Mort Subite.*) Wildberg relates a similar case, which is very striking on account of the circumstances in which it proved fatal. A woman having charged a neighbour with having pilfered herbs in her garden, an altercation ensued, which was brought to a close by the neighbour seizing her by the arms, shaking her violently, and shoving her away. She fell down, and in fifteen minutes expired. On opening the body it was found that a large vomica of the left lung had burst into that side of the pleura, and filled it with four pounds of bloody pus. (Prakt. Handbuch für Physiker, iii. 255.) It was ascertained that the woman had an attack of peripneumony a year before; but from that time enjoyed good health, except that she complained of trivial cough, and some tightness in the chest. Two similar cases are related in Sedillot's Journal by a French physician, M. Mouton. One was the case of a custom-house officer, who died almost instantly after making a sudden effort in getting on board a vessel; the other was that of a sailor-lad who was found dead in bed, having retired in good health the previous evening. In the former, the right lung was one entire mass of suppuration; in the latter it was almost entirely in a state of carnification. In referring these cases to peripneumony, it must at the same time be admitted that several of them may be conceived to be instances rather of chronic pleurisy and empyema, having occurred before the late improvements in the pathology of diseases of the chest had led to a more accurate diagnosis of them.

Of all the diseases, however, which are the subject of the present sketch, none are of such frequent occurrence as **organic diseases of the heart.** Diseases of the heart often exist for a long time without a single symptom to attract the attention of the patient or his friends, and often prove instantly fatal without a single precursory warning. Nothing can exceed the irregularity of the circumstances in which such diseases prove fatal. Not only may one man sustain, without inconvenience, an amount of organic injury which cuts short the life of another; not only may one suffer long and cruelly from the same affection in kind as well as degree, which kills another without a moment's previous suffering; but likewise one person may die of a limited extent or degree of a disorder which, in another, reaches an extraordinary height without giving a single indication of its presence. It is almost unnecessary to illustrate by examples statements so familiar to all practitioners. But as they are nevertheless apt to escape attention in medico-legal investigations, a few instances will be subsequently mentioned, which will at the same time place in a clear light the importance of the present description of diseases in the practice of medical jurisprudence. Meanwhile it may be mentioned that, as sudden death from latent organic affections of the heart is the most common of all the varieties of sudden death from latent diseases, so is it medico-legally the most interesting and the most important.

It would not, at first view, appear probable that **pneumothorax** ought also to be enumerated among diseases of the chest which may put on a latent course, and prove suddenly fatal. In the most frequent variety of it, which is occasioned by a softened tubercle opening a passage into a bronchial tube on the one hand, and through the pleura into the cavity of that membrane on the other, the progress of matters is usually marked both by the antecedent symptoms of tubercles in the lungs, and by dyspnœa and other symptoms which succeed the passage of air into the cavity, and precede the fatal termination for a considerable interval of time. But at times the antecedent symptoms of tubercles are obscure or wholly absent, and death takes place suddenly at the moment of rupture of the pleura and passage of air into its sac. The following interesting case, which occurred in 1831, in the clinical wards of the Edinburgh Infirmary, under the care of Dr. Graham, establishes the statement now made. An elderly man had been six weeks ill, and during four of these in the hospital, on account of a dyspeptic complaint, and never presented any symptom to draw attention towards the chest as the seat of disease. At length he suddenly complained of an uneasy feeling in the pit of the stomach, and expired at once. The left lung was all studded with tubercles, so as to be almost impervious throughout to the air, and consequently unserviceable in the function of respiration; the right side of the chest was filled with air, so that the right lung, itself not very materially tuberculated, was compressed, and thus rendered unserviceable also; and the air had obviously issued from a recent ulcerated opening in the lower lobe, establishing a communication between the sac of the pleura and a considerable bronchial tube. The cause of the man's sudden death was here quite obvious; and the whole circumstances of the case prove how pneumothorax may be the occasion of instantaneous death, where no reason existed for suspecting the presence of any of the pathological conditions in which it is known to originate.

This case leads to the observation, that **pulmonary tubercles** are very frequently latent for a very great part of their progress. So long as they do not undergo the process of softening, they may gradually invade a large portion of one or even of both lungs, without occasioning any material disturbance to the general health, or even so far disturbing the function of respiration as to attract forcibly the patient's attention. Cases even occur from time to time where tubercles of considerable size have softened and suppurated without the process being indicated by the usual outward symptoms, and without any marked disturbance to the general health. These facts are so familiar to every one who is extensively engaged in practice, — especially in hospitals, — that it seems unnecessary to illustrate them by any examples. The writer even knew an instance where numerous tubercles, evidently old, and some of them completely suppurated, were found in the lungs of a friend, who died of a totally different disease; namely, spreading cellular inflammation,

and who, till within a few days of death, was much addicted to athletic exercises.

Pulmonary tubercles, which have pursued a silent course, may even prove suddenly fatal; but in such cases there is always some accessory and obvious pathological condition superadded, which is the real cause of the fatal termination. One of these has just been exemplified; namely, pneumothorax. Another, of much more frequent occurrence, is rupture of one of the larger blood-vessels in the lungs, by erosion of its coats, occasioned by the proximity of a tubercle.

Diseases of the great vessels within the Chest come under the same designation with diseases of the heart, inasmuch as their course is frequently altogether latent, and their termination in death instantaneous. But in cases of instantaneous death, the immediate cause of death is always apparent in rupture of the vessel and sudden hemorrhage. It does not appear that diseases of the great thoracic vessels are ever circumstanced as in those frequent cases of diseases of the heart, where death takes place suddenly without any discoverable accessory pathological phenomenon, to explain why death occurred at the particular period, and not days, weeks, or even months before.

Of **Diseases of the Abdomen** there are several which may run a latent course for a very long time; but there are few which will remain latent to the last, like many of the diseases mentioned under the preceding heads.

Ulceration of the membranes of the stomach, proceeding from within outwards; ulceration of the intestines, of the same nature; ulceration of the gall-bladder, or of the biliary ducts; chronic organic derangement of the great secreting viscera, —more especially of the liver or kidneys; chronic disease of the coats of the large abdominal vessels; extra-uterine conception, of various kinds;—may exist for a great length of time, without occasioning any characteristic symptoms, or even, at times, any derangement of the health at all. In general, however, as they approach a fatal termination, they develop themselves fully by their external characters. But, on the other hand, they frequently prove fatal suddenly, or in a much shorter space of time than usual, in consequence of some incidental pathological change being produced during their progress. Rapid death, from perforation of the stomach or intestines; from rupture of one of the biliary ducts; sudden death from the rupture of a perforated vessel, or of a brittle spleen; or of an extra-uterine conception, &c., are more or less familiar illustrations of such a course of things. Of the last-mentioned remarkable and rather rare accident, the following important example occurred to the writer, a few years ago. The case was a medico-legal one; a judicial inspection having been ordered in consequence of various circumstances, which it is unnecessary to notice here, having led to a very strong suspicion of poisoning. The female died of a few hours' illness, referable, as it seemed, to irritation in some organ in the abdomen. She had enjoyed good health for some time before, except that four weeks previously she had miscarried about the middle of the second month of pregnancy. On dissection, the abdomen was found to contain several pounds of recently effused blood; and its source was a lacerated opening in a Fallopian conception, to all appearance in the course of the third month. The state of advancement of the ovum, the absence of the membrana decidua, and the exact correspondence in the appearances of a corpus luteum in each ovary, showed that the woman had had a twin-conception; one uterine, the other Fallopian. Another abdominal affection, which it may be right to specify as occasionally assuming the latent form, is the accumulation of worms in the intestines. Intestinal worms commonly occasion characteristic symptoms; and in some instances they have been known to produce death under symptoms of epilepsy, not merely in children, but likewise in adults. (Treatise on Poisons, p. 590.) But in other circumstances they have been observed to accumulate to an enormous amount, without their presence being suspected till the supervention of a convulsive affection, a short time before death; and in not a few instances worms have been found abundantly in the intestines, after death from some unconnected disease, although they were not indicated by any symptom during the life of the individual.

It is probable that various **Diseases of the Spine** may put on a latent course; but as the greater part of the organic disorders of this region of the body have been accurately discriminated only in recent times, facts are still wanting on the subject. Meanwhile it is well ascertained that *caries* of the bones of the spine, though in general it leads sooner or later to the production of symptoms which no observant practitioner can pass over or mistake, will nevertheless proceed at times to an advanced stage of its progress, and extend widely its devastations without any prominent sign of its presence being given forth. In one variety of it, which terminates in dislocation of the processus dentatus of the second vertebra of the neck, instant death may occur, where no suspicion existed of the presence of any disease in the actual seat of mischief. Under this head too may perhaps be arranged a very extraordinary case of sudden death related by Dr. W. Thompson of Edinburgh, where the individual, while recovering from an ordinary cold, was found dead in bed, and the only unusual appearance to be discovered was fracture and dislocation of the processus dentatus, without any disease in the bones or ligaments, and without the slightest possibility of a suspicion of violence. (Edin. Med. and Surg. Journ. xlii. 277.) In cases like this it may not always be easy to feel assured that the injury was not inflicted after death in the course of the twisting to which the neck is often subjected in opening the head.

The preceding remarks on the various diseases which may run a latent course must be taken by the reader as mere illustrations of the subject, and by no means as intended to exhaust the list. Other diseases are similarly circumstanced. But those which have been specified comprehend by far the greater number of them; and they have appeared to the writer, on reference to his own medico-legal experience, as well as to the valuable and extensive records of medico-legal cases in German and French journals, to be the most fre-

quent, and to bear the most important relations to medical jurisprudence.

The practical inference to be drawn from what has been already stated is, that, while latent diseases by occasioning sudden death frequently give rise to medico-legal investigations which are at once cleared up by the inspection of the dead body, we are not always entitled to infer, in circumstances of justifiable suspicion, that the discovery of such morbid appearances as indicate the pre-existence of latent disease will account for death,—that the latent disease was the occasion of death. For, during the latent period of the disease, death may have arisen from a different, perhaps a violent cause. This inference is not a mere theoretical deduction, but is amply supported by facts. For example, in Rust's Magazin is related the case of an apothecary who poisoned himself with prussic acid, and in whose body the lower lobe of the left lung was found consolidated and partly cartilaginous. (Mag. für die gesammte Heilkunde, xiv. 104.) In Corvisart's Journal there is a more remarkable case of a soldier who died of a few hours' illness, and whose right lung was found after death forming, it is said, one entire abscess,—the case being probably one of chronic pleurisy and empyema. Yet this man clearly died of poisoning with hemlock, of which he partook accidentally with several of his comrades; and it is not unworthy of notice, as a farther illustration of what has been said of pleurisy as a latent disease, that he daily underwent to the very last day of his existence the duties and fatigues of a military life. (Journal de Med. xxix. 107.) In Pyl's memoirs there is a similar account of a woman who enjoyed tolerable health, and died of a fit of excessive drinking, and in whose body the whole left lung was found in one mass of suppuration. (Aufs. und Beobacht. v. 103.)

One of the leading peculiarities which renders these singular cases important in a medico-legal point of view, in so far as it tends, on the one hand, to bring such cases forward in a medico-legal shape, and on the other to render the decision of them sometimes a matter of no small difficulty,—is that latent diseases are apt of themselves to prove suddenly fatal under the operation either of slight violence, or of the circumstances accessary to violence, such as passion, fright, struggling, and the like. The following are apposite illustrations. A foreigner, who was supposed to labour under no other disease except the natural infirmities of a rather advanced period of life, quarrelled one evening with his bed-fellow, and in the course of the quarrel received but one blow, which was inflicted with a stick over the back of the hand. But he immediately fainted, and in three minutes was dead. The heart presented induration of its valves, but in particular was unusually vascular throughout its whole substance, and was covered with a layer of coagulable lymph, clearly showing the pre-existence of one of the most common perhaps of all latent diseases, pericarditis. (London Medical Repository.) A more remarkable and much more difficult case occurred to the writer not many years ago. A pawnbroker who had for a long time been often and severely maltreated by his wife, returned home one afternoon very tired, and immediately afterwards was heard by a neighbour undergoing the customary domestic discipline. Fifteen minutes after he entered the house, a friend, who called for him, found him in bed in the agonies of death; and in a few minutes more he expired without having been able to answer any questions. His wife was accordingly apprehended under the charge of having poisoned him. A variety of medical as well as moral circumstances, however, precluded the idea of poisoning; and, although evident marks of the woman's violent conduct were visible in the shape of both old and recent contusions of the arms and legs, there was no indication of any violence adequate to occasion death; and the only way of satisfactorily accounting for death was by supposing, that amidst the circumstances accessary to the quarrel, he died of latent organic disease of the heart; for there was found, throughout the septum of the ventricles, and extensively also in the external parietes of the heart, a conversion of the muscular fibre into a substance resembling tubercular matter. Of this disease he had not presented during life a single symptom, although he was much accustomed to active exercise.

It is plain from the whole of the preceding line of statement, that in medico-legal cases involving the question of sudden death from latent disease, something more will be necessary for elucidating their nature than the mere discovery from appearances in the dead body that a latent disease had existed. In cases of death from obscure causes, it is in general considered sufficient in ordinary practice to explain its nature, if appearances are found in some important organ of the body of a kind which clearly indicates pre-existing disease. But this loose habit of inquiry will not answer in the practice of medical jurisprudence, for the appearances may be those of a disease latent to the last, and death may have arisen from a cause of a totally different nature, — possibly from the very kind of violence which is suspected to have been applied. It is necessary therefore to obtain some further evidence of the connection of the morbid appearances with the fatal event, otherwise we are not entitled to say that the cause of death has been natural.

The evidence to this effect may be taken from a variety of sources.

1. The first and most satisfactory evidence is where the morbid appearances indicate that the disease has brought into action one of the proximate causes of death, — that derangements of structure or function have been induced which must have been incompatible with the continuance of circulation or respiration. Thus we can have no difficulty in pronouncing the occasion of death to have been latent tubercles, where there is found along with tubercles either apoplexy of the lungs in connection with an opening in a large vessel, or pneumothorax attended with the peculiarities mentioned in a preceding part of this article. The cause of death is equally clear where chronic disease of a large vessel has been brought to a close by perforation of its coats and the discharge of several pounds of blood into the chest, or where latent disease of the heart has terminated in effusion of blood into the pericardium and stoppage of the heart's action by mechanical pressure. It is not often, however, that evidence

of the kind now referred to can be obtained. It happens much more generally that morbid appearances, which in ordinary professional language are said to be sufficient to account for death, are nevertheless such both in kind and degree as indicate an amount and progress of disease which numerous facts have proved to be quite compatible with the further maintenance of life, or even with apparently good health.

2. The next kind of evidence is furnished by certain peculiarities in the morbid appearances, which, though not, according to our knowledge of the animal functions, incompatible with the continuance of life,—and not indicating that any of the proximate causes of death have been brought into action,—nevertheless are known by experience seldom or never to occur except where death does immediately or speedily follow. Thus, where in a case of sudden death, the circumstances immediately antecedent to which are unknown, a recently completed perforation of the stomach or intestines be found, or a rupture of the gall-ducts or gall-bladder, and effusion of the contents of the ruptured organ into the peritoneum, death from this concatenation of causes may be safely inferred. It further appears from various cases, of which a few have been related above, that the same inference may be drawn where an extensive abscess of the lungs seems to have just burst into the cavity of the pleura through the investing membrane of the lungs. We cannot exactly say why death should supervene rapidly in such circumstances; for it often ensues long before inflammation can arise in the membrane with the surface of which the foreign fluid comes in contact: but the fact is undoubted that speedy death is almost invariably the result; and this fact may fairly be made the basis of induction where the circumstances preceding death are unknown or doubtful, and an opinion must be formed on morbid appearances alone.

It would be a matter of very great importance to discover some peculiarity of the kind we are now considering, in the instance of cases of sudden death from latent diseases of the heart. No species of sudden death is more common; yet pathologists have not yet furnished any explanation of the immediate cause of death. Does it arise from sudden paralysis of the heart, or from spasm, or sometimes from the one, at other times from the other,—from excessive gorging of the heart's cavities, or from the blood not being supplied in sufficient quantity? Or, leaving these questions in pathological physiology, by what characters, either in the morbid appearances or in the circumstances collateral to them, such as the state, quantity, or seat of the blood, may it be ascertained that an organic affection of the heart, presented to view in a case of doubtful or suspicious death, has or has not been the occasion of death? This query may probably receive a reply after a more careful examination of the appearances where death has unequivocally been produced by disease of the heart; but at present it must remain unanswered.

3. Another description of evidence by which death may be presumptively connected with morbid appearances found in the body where the cause of death is obscure, is derived from the occurrence of symptoms immediately before death, which correspond with the appearances discovered. Thus, where an individual dies under symptoms of sudden dyspnœa, and an extensive chronic pleurisy or peripneumony is found in the dead body, death is clearly to be referred to the latent disease. The same inference is allowable where symptoms of fainting precede death, and the appearance found is organic disease of the heart, or where coma and convulsions immediately precede dissolution, and suppuration and softening of the brain, or the traces of chronic meningitis, are discovered. In many cases of this kind, however, regard must also be had to the particular species of violent death which may happen to be suspected; because it may be that the symptoms antecedent to death are common both to the natural and the violent cause.

4. Hence, in many instances, before inferring death to have arisen from a latent disease, of which the traces are found in the dead body, it is farther necessary to determine, by as many proofs as the nature of the case will supply, that violence is improbable, if not out of the question,—and in particular, that the circumstances will not bear out the suspicion of the particular kind of violent death which is imputed. It is seldom that cases occur where this cannot be done, provided a skilful use be made of those mixed medical and general circumstances which no one but a medical man can properly collect or appreciate, but which, at the same time, it is right to observe that even medical men are apt to overlook or mismanage, from insufficient acquaintance with the principles of medical jurisprudence. This observation applies with peculiar force to that very common class of medico-legal cases where extraneous circumstances, in the instances of sudden death from latent disease, have given occasion to a suspicion of poisoning. A skilful toxicologist, who is also a medical jurist, will almost always discover proofs enough to decide the question of poisoning.

5. Additional information, by which much light may be often thrown on medico-legal cases involving the question of sudden death from latent disease, is derived from attending to the collateral conditions under which latent diseases are usually observed to prove suddenly fatal. These conditions are at least three in number. Many cases of latent disease have their symptoms first developed, or even prove suddenly fatal, during the additional constitutional disturbance occasioned by a fresh disease. Thus, it is not unusual for death to take place suddenly, in the early stage of convalescence from other diseases. A few years ago, a convalescent in the Royal Infirmary, an athletic young man, who was recovering from a slight attack of fever, followed by a relapse, suddenly called aloud for help, dropped down deadly pale, and died apparently in a faint; and on dissection, there was found considerable enlargement and hypertrophy of the heart, with complete adhesion of the pericardium. This is a single characteristic instance of an incident by no means uncommon in hospitals. A second still more common circumstance which concurs with sudden death from latent disease, is some unusual or violent exertion. Several of the cases mentioned above, in illustration of various general facts, will likewise illustrate the present statement. The

two following, which are related by Lancisi, are also excellent additional examples. A corpulent footman, liable to occasional dropsy of the legs, unequal pulse and uneasy breathing, dropped down dead one day while running after his master's chariot. The heart was much enlarged, particularly the right ventricle; and the left ventricle, usually empty of blood after death, was found much distended, as if it had been unable to expel the blood which was transmitted to it. (De Mort. Subit. i. 46.) Another footman, subject to palpitation and difficult breathing, yet so little incommoded as to be able to run habitually with his master's chariot, died suddenly after coition; and Lancisi found the heart enlarged to a size exceeding that of an ox. A third condition, in which latent diseases have been known to prove suddenly fatal, is during some violent emotion of the mind. This circumstance is even sufficient to occasion death, where the immediate cause of that event is some new accessary derangement of structure incompatible with the farther maintenance of life. It is a common cause, for example, of rupture of the great thoracic vessels. An interesting medico-legal case of this nature has been related by the late Professor Chaussier. Two men, who had been long on bad terms with each other, met one day in the street, when one of them, who was on horseback, struck the other across the shoulders with a whip. The man who received the blow immediately pursued the rider in a tempest of passion; but he had scarcely advanced a dozen steps when he dropped down, muttered a few indistinct words, and died. Many people witnessed the affray, and they all believed the deceased had been killed outright by the blow. But on the body being examined, no outward mark of injury could be seen; and it was subsequently found that an aneurism of the aorta had burst into the cavity of the chest. It is plain from the case formerly noticed of sudden death from latent pericarditis during a quarrel, as might likewise be reasonably inferred from physiological considerations, that latent diseases may prove suddenly fatal during violent emotions of the mind, even though no new accessary pathological injury be occasioned.

The general result of the observations on the present head of evidence seems to be, that any circumstance which produces either sudden violent excitement or sudden violent depression of the circulation, may cause instant or speedy death, where extensive organic derangement has accumulated silently in any of the important organs of the body.

By attending to one or other, or several of the criterions now laid down, it will seldom happen but that an opinion, strongly presumptive, if not even positive, may be formed on the question of the cause of death in the cases which are the subject of the antecedent comments. In some instances, however, this is impracticable; and an excellent illustration is the singular case noticed above of instant death after a blow, where there was extensive serous effusion into the ventricles, the effect probably of chronic latent meningitis. The circumstances of death were conformable with the idea of sudden death from violent passion, operating on a frame already brought to a peculiar condition by latent disease; for it was proved that the old man was in a state of high-wrought passion, in consequence of the misconduct of his son. But it may also be readily conceived that a blow on the head might have the same effect, though quite insufficient to occasion such a result in ordinary circumstances. The prisoner was found guilty of culpable homicide, and transported for life.

R. CHRISTISON.

LEGITIMACY. (See SUCCESSION OF INHERITANCE.)

LEPRA. — Λέπρα: from λεπρὸς-ρὰ, *scaly; th.* λεπὶς, or λέπος, *a scale.* A scaly disease of the skin, occurring generally in circular patches. At a very early period of medical literature, the confusion, which afterwards became "worse confounded," began to reign concerning the terms *lepra* and *leprosy.* The Arabian physicians had described the tubercular elephantiasis, the elephantiasis of the lower extremity, and some varieties of scaly disease, under distinct appellations, which became frequently misapplied. When, at the revival of learning, the works were rendered into the European languages, the Latin translator multiplied the perplexity by interpreting the Arab word *juzam* by the term *lepra,* which the Greeks had applied to designate the scaly disease defined above. In the middle ages the term leprosy was indiscriminately applied to the different forms of elephantiasis, the scaly diseases, and, in fact, to any form of chronic skin-disease which was bad enough to entitle the subject of it to admission to the lazar-houses which were established over Europe at that time, where the indigent were glad to get the subsistence they provided at the expense of being called lepers. This confusion has been a subject of complaint with writers from age to age, yet it became perpetuated. Hensler's learned treatise,* written with a view to elucidate the subject, left it nearly as complicated as ever; for he and Sprengel treated under the term leprosy the various forms of elephantiasis, the Greek leuce, and the proper scaly lepra. Many modern writers do not appear to desire the removal of this obscurity, as they persist in describing the former of those under the name of leprosy. We trust, however, that medical men will now see the expediency of adhering to Willan's correct nomenclature in this instance, which restores to the term lepra its proper and original signification, namely, the scaly disease, the subject of this article.

History of the Disease. — Lepra generally begins on the extremities, below the larger joints, where the skin covers but thinly the tibia and ulna respectively. It commences by small, roundish, smooth points, slightly prominent above the surface of the skin, which soon become red and shining from being overlaid by minute transparent scales. These become soon detached and replaced by others. The eminences by degrees enlarge; the scales become thicker, and are chiefly formed on the circumference of each spot. They observe the circular form in spreading, and attain the size of a shilling or a half-crown piece; and as they increase, the circular border becomes raised and en-

* *P. G. Hensler.* Vom Abendländischen Aussatz im Mittelalter, nebst einem Beitrag zur Kenntniss und Geschichte des Aussatzes. Hamburg, 1792

closes a red area, which is free from the squamous development. A red areola is also perceived external to the raised circumference where the scales collect. These orbicular patches, in spreading, touch and intersect one another; and though in this stage the circular form is lost, we may still trace the segments sufficiently well to show their original conformation. They unite usually first at the elbows and knees, the parts, as we have said, where the disease first shows itself. In the progress of the affection, while the existing patches are enlarging in this manner, new ones arise; the abdomen, the back, and the chest become affected; and in some cases it spreads to the head, face, and hands.

The scales fall off and are renewed very frequently. Sometimes they are so easily detached and form so rapidly, that the patient's clothes and bed are filled with scales, which cause some irritation: in other instances they adhere more firmly, and accumulate in such quantity as to impede the motions of the joints,—a still greater source of troublesome annoyance.

By their multiplication the scales become aggregated apparently in an irregular manner; yet each one is propagated from a centre, and is attached by a pulp to the dermoid tissue: this fact is proved by tearing one off, when a slight red speck is seen to project from the middle of the inferior surface, corresponding to a depression in the spot whence it has been displaced. When the disease has lasted long, or is in process of cure, the scales, as they fall, present the reticular eminences proper to the cuticle, and leave the surface red, smooth, and marked by corresponding reticulations.

The description here given will apply to the great majority of cases of lepra, but it presents varieties derived from its extent, duration, and treatment. The accidental circumstances of situation and colour also impart to it certain peculiarities.

It sometimes covers the whole body, commencing for the most part from the extremities; it begins usually on the two arms and legs at once, and propagates itself, as described, to the trunk; it rarely spreads to any extent on the face: the forehead, the temples, and the external angles of the orbits are, however, often the seat of some scaliness spreading from the hairy scalp. When the scalp becomes affected, the scales are very minute, and generally cover an exudation derived from the inflamed bulbs of the hair; a moisture is also remarked to accompany the scaliness when the disease invades parts where there is a necessary friction, or places furnished with many sebaceous follicles,—as the nates and inside of the thighs, the axilla, the verge of the arms, &c. These form exceptions, however; for it is one of the essential characters of the disease that the desquamation is quite dry.

In cases of a very chronic nature, where the disease is of such extent as to spread over the hands and invade the root of the nails, these become much altered in structure, curved, and of a dirty yellow colour. It has been observed in some rare instances that the dermoid tissue which secretes the nail has become inflamed and furnished a sanious discharge. (*Rayer.*) In the cases which are complicated by any of those accidental secretions, the lymphatic glands sometimes inflame and swell, as Richter remarks; but we cannot admit into the description of lepra the rhagades and ulcerations which are mentioned in his excellent work. (Specielle Therapie, vol. vi. p. 440.)

A remarkable appearance which lepra sometimes assumes has induced accurate observers to recognise in it a peculiar species of the disease. It has been observed on parts of the trunk that a complete desquamation over a considerable surface takes place without being followed by any reproduction of scales in this particular place: it remains red and smooth, and still affects the circular form; and not only is the whole area round and bordered by a slightly raised margin, but it contains within it some patches, either circular or obviously showing a disposition to that form, yet without scales either on the centres or the raised borders — their usual nidus. What makes this variety more remarkable is, that whilst the patches exhibit this feature probably on the back, it is as scaly as ever on the extremities. We must not, however, suppose that this partial absence of scaliness in such rare cases makes any exception worth notice in the history of lepra; in some instances it probably depends on idiosyncrasy, but we think it is more frequently a partial curative effort of nature, or the effect of medicine, which from some unaccountable cause is arrested after having proceeded only so far as to check the morbid secretion of the cuticle, the vascularity still remaining. This explanation is rendered the more plausible if we consider the locality of the phenomenon, and the manner in which the disease usually advances towards a cure in the cases where we can trace its disappearance under the influence of medicine. Its situation, as we have said, is on the trunk, almost invariably on the back; and it is here that, when lepra begins to yield to any of the methods of treatment to be mentioned afterwards, the effect is first visible.*

The constitutional disturbance attending on lepra is for the most part very trifling, particularly when we consider the large cutaneous surface which is frequently engaged; sometimes a slight fever, accompanied with gastric symptoms, coincides with its first attack; but when established, it goes on for months and years without constitutional symptoms of any import arising from it. Its most troublesome accompaniment is a disagreeable pruritus, which attends its commencement and increase. This occurs particularly when the circulation is excited by exercise or full diet, and when the warmth of bed exalts the cutaneous action: it is sometimes aggravated to a burning heat which is most intolerable. This itching and tingling is not peculiar to lepra, but is met with in most diseases of the skin attended with inflam-

* It appears to be a law in pathology that the resolution of a disease commences from the place to which it has last extended: of this pneumonia is an instance familiar to stethoscopists, yielding first where it is most recent. It also sometimes affords an example of a state which we think is analogous to the appearance of lepra which we are discussing,—we mean those cases which will, no doubt, present themselves to the memory of accurate observers, where the pneumonia, after proceeding a certain way towards resolution, remains stationary, neither going backwards nor forwards. This appears to us to be the nature of the appearance adverted to particularly by MM. Cazenave and Schedel.

mation, and is often present in a greater or less degree as a symptom of internal disease. Mr. Plumbe's explanation of this phenomenon is too mechanical, and, though ingenious, inadmissible. He thinks that it is to be referred to the raising up of the scales by the increasing development of the "inflamed margin, and fresh growth of scales, the centre which was attached to the cutis being thus forcibly torn from such attachment." He supports this opinion by the observation that the pricking occurs most constantly at the commencement, when the new scales are oftenest detached, and seldom happens when the disease is subsiding. We consider this pruritus to be a morbid sensation, depending probably on an altered secretion in the skin, and the reason appears to be very obvious why it happens in the commencement. The morbid secretion which forms the scale affects the sensibility of the skin more strongly at first, when the impression is new, than afterwards, when the squamous deposits become an accustomed stimulus to it; and besides at this period the cutaneous sensibility becomes somewhat impaired: the subsidence of the disease is of course not marked by pruritus, as the vascular irregularity producing the scaly secretion is now returning to the physiological state. This explanation is applicable to the itching and tingling of other cutaneous affections, and to that which is symptomatic of hepatic and other visceral derangement.* Hippocrates remarked that the pruritus increased before rain.

Although much constitutional disturbance be rare, yet if lepra spread over the whole body, and is severe in degree, it often produces some anxiety and febrile excitement, partly from the general extension of the sub-inflammatory state of the skin, and partly from the mere mechanical annoyance that the scaly incasement gives rise to by obstructing the free motion of the joints, which become sometimes painfully tense, and so stiff as to oblige the patient to keep his bed.

Willan and Bateman, endeavouring to systematise different terms used by the Greek writers, divide their genus lepra into three species, a division which is considered unnecessary by the most judicious writers. Their lepra vulgaris is the disease we have described here, and comprehends all the varieties.

Lepra alphoides is a mere variety of the common lepra, possessing the same essential characters, and requiring similar treatment. It is a form in which there is less redness of the skin and elevation of the circular margins: the scales also are smaller, and of a more pearly whiteness. It seldom reaches the trunk, and it generally attacks children, aged persons, or those of a weakly habit of body. It appears to be a variety of the disease in which the morbid action is less energetic, modified probably by some constitutional peculiarity.

Lepra nigricans is confessedly a rare form. M. Biett insists that this has invariably a syphilitic origin, and we agree with him in this view of it.

Secondary syphilis, as it assumes almost every form of cutaneous disease, appears sometimes under that of lepra. It is a question with pathologists whether the syphilitic diseases of the skin are to be separated from the others in nosological arrangement: they agree in anatomical characters, put on the same form, and in many instances yield, temporarily at least, to the same treatment. Notwithstanding these points of agreement, however, the most esteemed authors consider that they should form a separate class. Their venereal origin furnishes a much more important reason for distinguishing them than any consideration arising from their agreement in form affords for keeping them together, as it is an indication for a special line of treatment, the disregard of which might be attended with disastrous consequences.

Lepra more commonly affects men than women, but the difference as to sex is inconsiderable. Youth and middle life are more liable to it than infancy or old age; but no age is exempt from it, after the first dentition to the latest period of life. It appears to be less affected than the other skin-diseases by the influence of seasons; but it is observed to be most common in autumn. Differences of condition and circumstances in life have not a decided influence on it, except so far as they favour the development of the predisposing cause. Willan considered cold and moisture to be a frequent cause of it, and says that it is often excited by external irritants and dry sordes on the skin. Bateman differs with him in this, as he has seen it frequently in persons whose respectable rank and circumstances precluded these causes, while he has not observed that certain classes of workmen, necessarily exposed to them, were particularly affected with it. Like the other cutaneous diseases, it has been known to succeed to a disordered state of the digestive tube and of the biliary organs; but we must consider in these cases that there has been a great predisposition present; and it is one of the diseases where the latter acts a principal part. Where a predisposition prevails, the slightest causes are sufficient to give rise to it; thus it has been produced by highly seasoned food, spirituous potations, violent exercise, and strong emotions of the mind; anger is said to be a frequent exciting cause of it: mental depression also produces it, especially that arising from unexpected poverty and the bad diet accompanying it, as in the interesting case narrated by Dr. Mackintosh. (Practice of Physic, vol. ii. p. 217.)

It is quite certain that lepra is not contagious; and discussions on the subject could only have been entertained when a total disregard of precision permitted diseases of the most distinct nature to be classed under this most abused term.

Pathology.—It is sufficiently obvious from the enumeration of occasional causes, that we are not aware of any determinate conditions in its origin. That lepra is an inflammatory disease there can be no doubt; but as the term inflammation does not convey any very defined notion as to proximate causes, this is but a vague account to give of its etiology. We cannot in fact conceive any change taking place in the organization of the skin without a change in the organic action

* There is an analogy between those morbid sensations of itching, pricking, tingling, &c., and the muscæ volitantes, flashes of light, and tinnitus aurium. They are all irregular impressions on the sentient extremities of the nerves; in the latter on those of vision and hearing, in the former on the nerves of touch. Diseases of the chylopoietic viscera and the brain give rise to both classes of vitiated sensations.

of its ultimate tissue or capillary vessels; and wherever this takes place, it constitutes a phenomenon which has hitherto been denominated inflammation. Observation of the mottled arms of healthy infants shows that the cutaneous capillaries in their physiological state affect something like an orbicular arrangement; and this might be in some measure connected with the fact, that most inflammations of the skin originally observe a rounded form. Further than such a simple step, however, our knowledge does not permit us to advance in the etiology of this, or indeed of any other skin-diseases. In Mr. Plumbe's work an attempt is made to ground the pathology of cutaneous diseases on the part of the dermoid tissue affected, and to specify the class of vessels diseased in each morbid alteration. This would be very desirable, but is wholly unattainable in our present state of knowledge. Anatomy teaches us hardly any thing about the arrangement of the capillaries of the skin. We are totally ignorant as to whether there be separate vessels for the secretion of the tissue of the corium, the rete mucosum, and cuticle; and whether the transpiration and sebaceous matter are furnished by these, or have separate vessels for their elaboration: it is gratuitous, therefore, to say that the seat of the inflammatory action which constitutes lepra is in the vessels which secrete the cuticle, merely because cuticle is the product of the inflammation; for this is to assume that the different tissues are formed by different vessels, a conclusion which has never been proved, and which modern physiology gives reason to suspect is untrue. If the argument were admitted, it would infer a separate set of vessels for every product of inflammation of the skin. It is, however, unsuitable to proceed with a discussion of this nature in this place.

Diagnosis.—The disease which most resembles lepra is psoriasis. The earliest observers of squamous diseases marked the difference which exists between them. Paul of Egina marks the distinction which depends on their form, in these words: "Λέπρα per profunditatem corporum, cutem depascitur *orbiculatiori modo*, et squamis piscium squamis similes dimittit. Ψώρα (psoriasis of the moderns) autem magis in superficie hæret, *varie figurata est*;" but if no other difference existed than their configuration, we might be induced to follow the example of some respectable authorities, and to describe them together as mere varieties of the same disease. They differ, however, in more essential respects. Lepra is a more chronic disease than psoriasis, both as to duration and effects; it does not excite the same amount of sympathetic disturbance in the constitution, and is less affected by the relations of temperament, seasons, climate, &c.; in fact when it once sets in, it appears to become more inveterately wedded to the constitution than its congener, which, although it produces greater local and general irritation, is yet more amenable to the resources of medicine. Its general aspect, indeed, sufficiently distinguishes it from every species of psoriasis except one. The circular margins enclosing the central red part free from scales are quite contrasted with the irregular scaliness of psoriasis, cracked often by rhagades and ulcerations. The psoriasis guttata, however, appears to be a near approach to the character of lepra, and to constitute a natural alliance between them: the same round spots, gradually increasing and becoming covered with scales, characterize both, but it is only at the very first stage and at its declension that they are very similar; for when it is fully formed, the patches are much larger, and have assumed the annular form mentioned above, whereas the smallness of the patches, their *whole* surface being covered with minute furfuraceous scales in psoriasis, is sufficiently characteristic, so that whilst their agreement in some things shows them to belong to the same family, yet there appear to be sufficient points of peculiarity in each to enable a careful observer to make a tolerably confident diagnosis. Several eminent writers are strenuous advocates for their being united on the grounds of similarity, and lean much on the fact that sometimes in psoriasis there are present some patches which have all the characters of lepra. We acknowledge this fact, but we do not think it a valid argument, as it would hold good for uniting many cutaneous diseases which all agree to separate, as, for instance, eczema and impetigo, because the vesicles of the former are frequently intermixed with the pustules of the latter. While, therefore, we acknowledge their affinity, and that their treatment is similar, yet, from the differences detailed above, and these as particularly affecting their prognosis, we are for maintaining them distinct, and the weight of authority is on our side.

There is a possibility of confounding some other diseases, which affect a circular form, with lepra. In the state of the ring-worm of the scalp, when the purulent incrustations are detached, a red ring remains, which is sometimes covered with a slight scaliness. This might be mistaken for a lepra of the scalp, and the more so if the porrigo be a little developed on the body; but a little attention will detect the difference between the aspect of the ring-worm and the leprous patches; the former is covered over with a small laminar scab rather than a semi-transparent scale: the hair, which falls in the ring-worm, is preserved in lepra, and a few days' watching will develop the favous pustules from which the scab is secreted. If contagion can be established, as it generally can in the porrigo scutulata, it decides the question at once; but the chief element in the diagnosis is derived from considering that it is much rarer for the porrigo to be found on the trunk and extremities, than for lepra to be seen on the head, and that respectively they for the most part spread in contrary ways, the lepra from the extremities and trunk to the head, the porrigo from the head to the body. (*MM. Cazenave et Schedel*, Maladies de la Peau d'après M. Biett.)

With respect to the syphilitic eruptions which assume the guise of lepra, their diagnosis is not difficult, and this fortunately, as it is of more importance to be positive in this case than the former, the consequences of mistake being much more serious. The syphilitic squamous disease, called by Willan and others lepra *nigricans*, represents the figure of lepra; but the violet, coppery, or black colour, which is its essential characteristic, is quite sufficient to stamp its origin. The round, flattened, circumscribed concretions constituting the tubercular syphilis, called some-

times by us incorrectly pustular eruption, might impose on us also for lepra; but here the coppery colour, which is happily for our diagnosis an inseparable companion to the venereal taint, comes again to our aid. But even if we had not this unerring distinction, a little examination evinces that the tubercular spots, although disposed in rings, are very different from the circular patches; and the thin squamous lamina, which is sometimes observed on the tubercles, is disposed just the reverse of the leprous scales: it spreads from the centre, and is only a partial covering, never large enough to conceal the circumscribed induration which projects beneath.

Prognosis.—Lepra is to be reckoned, under the most favourable circumstances, as a disease very difficult of cure, and in many cases incurable. In old or debilitated subjects, scarcely any means are sufficient to eradicate it; but in those of an opposite habit success is never to be despaired of, as there are many cases on record of its being quite removed after twelve and sixteen years' standing. It is not dangerous when it is a primary disease; for even when nearly the whole skin is encased by its scaly concretions, the injury of its function seldom involves the system in general disorder. This is a statement of a general rule, to which, of course, exceptions will be found in those whose organization is bound together by a greater sympathy—idiosyncrasies* of constitution, which it is impossible to foresee as it is to explain when developed. The obstinacy with which it adheres when once engrafted on the system, shows itself sometimes by the inefficacy of every means to prevent it spreading over the whole body; and again, in other cases it disappears spontaneously or under the influence of medicine, in one place, and while the patient is congratulating himself on its departure, it suddenly appears in another part of the body. On the other hand, it has been known, after lasting for months, or even for years, gradually to subside of its own accord under the influence of some of those inexplicable changes to which the human body is liable. It appears to have sometimes gone on to a fatal termination; and the description of its ultimate encroachment on the vital functions, while it suggests phthisis, presents some singular features. "The local disease having reached its highest degree, a remarkable constitutional affection appears. The patient now becomes very languid; asthmatic, particularly at night-time; smothering fits seize him; he coughs violently and spasmodically, and spends the night in perfect sleeplessness, falling into excessive, colliquative, clammy sweats, which give an intolerably fetid odour. His voice becomes weaker and hoarser; the appetite for food and drink is preternaturally increased; and the temper becomes gloomy. Finally, various nervous symptoms arise, faintings, convulsions, paralysis of some parts, and death arrives preceded by the highest degree of exhaustion." (*Richter*, Specielle Therapie, vol. vi. p. 440.)

Treatment.—The history of the treatment which has been from time to time employed presents a picture of the prevailing medical dogmas, and at the same time indicates the obstinate nature of the disease; for where so many various remedies have been lauded for their success, it only proves that experience has not established that any one has been generally successful. It would take up a large space to furnish a mere catalogue of the various substances which the three kingdoms of nature have been ransacked to supply for the cure of this disease in different ages. Empiricism, aided by superstition, was, in the early times, perpetually devising something new from the animal kingdom; from the flesh of the harmless ass, recommended by Hippocrates and mentioned with applause in the writings of T. Bartoline, and the bull-frogs of Myzaldus, to the poisonous viper, which Galen hails as one of those great discoveries which accident has furnished to mankind. (De Simpl. Med. Facult. lib. xi.) In the vegetable and mineral kingdoms, almost every article used as a drug has had, at one time or other, its favourers, from the most innocent herb to arsenic; and each has been extolled as a specific. In describing the treatment, however, we shall only take notice of those remedies of which the efficacy has been proved by the experience of men who have made their therapeutic virtues the subject of investigation since cutaneous diseases have been studied after the modern improvements in pathology.

One great reason why remedies have been extolled beyond measure by some as certain specifics, and denounced unmeritedly by others as quite useless, is, that former writers have mostly neglected to mark the particular features of each case in which their remedy succeeded or failed. Having determined that it was *the leprosy* they had to do with, they appear to have gone to work with their favourite nostrum, without taking into account, or at least without recording, the most important therapeutical indications of the affection.

The first grand consideration in a rational treatment has respect to the cause. Can we trace its dependence on any internal disease? If so, it is vain to expect its cure until the primary disorder be successfully attacked; while it is unpathological to make it the object of *chief* attention: we say chief, because, although only a symptom, yet it is not, even in this case, to be entirely neglected, as its reaction may have a powerful influence on the original focus of the disease, and this in two ways, which it is highly important to distinguish. Its appearance on the skin may afford a salutary natural derivation, and in this case it would of course be injurious to endeavour by treatment to repel it: in another instance the disease of the skin may be only an additional source of morbid action, and react on the primary affection in a prejudicial manner; so that here, although but a secondary phenomenon, it must become an object of treatment. It is only tact and much observation that can discern these different circumstances; they do not often, however, fall under consideration, as lepra is one of the cutaneous inflammations least frequently complicated with organic disease of the viscera.

It needs scarcely be mentioned that if the skin affection can be traced to any external cause, whe-

* We owe an apology for the use of this word, which is, indeed, but a confession of ignorance, although cloaked by so learned a term. It really means that the fact which is referred to it cannot be explained by any recognised law in pathology.

ther it be mechanical irritants peculiar to any trade or locality, or endemic agents operating through the atmosphere, the patient must be withdrawn from their influence. Thus, if it occurs from the influence of a cold and moist climate, or that it can be imputed to sordes on the skin, (both which circumstances Willan reckoned as common causes,) in the first instance the patient should remove to a dry atmosphere; and in the latter he should change his occupation to some that would not necessarily expose him to the exciting cause; and it is the medical man's duty, if he have ascertained any of these sources, to insist upon the absolute necessity of taking this step, being aware that the comfort which flows from health may be taken from the patient for the remainder of his life if he neglect it.

The cause being investigated, and the treatment with respect to it having been considered, the age and constitution of the patient, and the extent and duration of the cutaneous affection, are the circumstances upon which we ground our judgment in proceeding to apply remedies for its cure. If the patient be young and strong, (and lepra usually occurs in such patients,) general bleeding must be performed; and if the disease has not become very widely extended, and inveterately chronic, the abstraction of blood by the lancet will frequently be attended with great benefit. The application of leeches in the neighbourhood of the leprous patches is also very effectual; and the disease in some instances yields to a few general bleedings, accompanied by leeching. The local bleeding by leeches is inadmissible when the malady has extended over the whole or a great part of the body; but when it is confined to one or both arms or legs, we can speak in the most decided manner of the great benefit derived from their use. In the comparatively recent cases the application of leeches two or three times, preceded by abstraction of blood from the arm, will be generally followed by a great diminution of the central and external redness and of the desquamation; in fact, sometimes by a speedy disappearance of the disease without the use of any other measures of importance.

The circumstances which peculiarly demand the abstraction of blood are, an active irritable state of the patches, and the existence of feverishness or great uneasiness from the prickling sensations; but it has of late years been proved that bloodletting is an excellent adjuvant to other means. In fact, a great improvement in the treatment of skin-diseases generally has taken place since the utility of bloodletting has been recognised in reducing the inflammation from an active to a passive state. It will much facilitate the cure of even the smallest extent of the disease to begin by a good bleeding; but it is in cases where it has spread very generally over the body that the bleeding is to be mainly depended on, at least at the outset of the treatment.

Dr. Duffin, whose large experience of this remedy is very favourable to its use, after pointing out its striking usefulness in the circumstances adverted to above as peculiarly requiring it, adds, "but supposing that there exist no general symptoms, still this mode of treatment is very often proper, were it had recourse to with no other view than to subdue the irritability of the skin or its extreme susceptibility to disease. But it has another good effect—it induces a state of the system that admits of being much sooner affected by the use of arsenic, when the active symptoms have been so far subdued as to allow of the employment of that medicine." Its effect as a preparative is, indeed, the chief improvement we alluded to; and since it has been so employed, many remedies whose efficacy was much debated are now found decidedly useful, their exhibition being preceded by a bloodletting, and recourse being had to it during their use occasionally, if any symptom of the active inflammation re-appear. It would be obviously improper to employ it if the patient be in a debilitated state, the effects of a bad constitution, of the long duration of the disease, or of old age.

Amongst the external remedies the bath is indisputably the most effective, and most generally used. The simple tepid water is very much employed, and is not superseded by the many new methods of bathing or vapourizing the surface. The painful stiffness and irritation are almost always relieved by a twenty minutes' immersion in water at 90°: it appears to us to promote cleanliness, and a softening and falling off of the scales, just as well as the vapour-bath; but the latter is preferred by many experienced practitioners. The tepid salt-water bath is still more effectual as a stimulant to the skin; but it is to be used only when the inflammatory state has been entirely removed by the antiphlogistic measures.

Much expectation had been raised as to the efficiency of medicated vapours in this and the other squamous diseases; but their superiority to the ordinary baths has not been demonstrated. The sulphur vapour-bath is the most powerful stimulant amongst them, and it has certainly been used successfully in some obstinate cases; it must, therefore, be kept on the practitioner's list, to be employed where other remedies are inapplicable or have already failed. The vapours of tar and of acetic acid have been much used, but they are not so highly esteemed as those of sulphur; but, indeed, experience has not established for any of those fumigations the virtues which were proclaimed at their first trials. Bathing in the medicinal waters containing sulphur, such as Harrowgate, Lucan, Leak, St. Gervaise, &c. is decidedly a means of great power in scaly diseases, and many extraordinary cures are attributed to their use. When they are recommended, and the patient cannot remove to any sulphurcous spring, a useful substitute may be readily made by dissolving six ounces of the sulphuret of potash in ten gallons of tepid water, and adding a small quantity of the sulphate and muriate of soda (eight ounces of each.) Bathing, however, whether it be local or general, and medicinal fumigations, are only to be relied on as a secondary remedy; they are not to be used till the active irritation be removed by depletory measures; and it follows from this that they are particularly applicable in the chronic cases, and in patients of a debilitated habit, where the disease is but little energetic: they must be persisted in for some time to produce a beneficial effect, and the vulgar opinion that they weaken the constitution is to be entirely disregarded, for

the contrary is the fact, as the patients will be found to derive strength from every means that exerts a salutary influence on the cutaneous disease. In many states of the skin where tepid bathing is advisable, its action will be much aided by gentle friction with a soft flesh-brush, the use of which is deservedly extolled by some writers.

Topical applications in the form of ointments and lotions are very useful in many cases. They are intended either to allay irritability, or, from their stimulating effects, directly to attack the disease by altering the action of the skin. In the former kind is reckoned the Carron liniment, which, spread over the leprous patches has been found to cool the skin, and keep it soft and comfortable; the addition of two drachms of oil of turpentine to eight ounces of it, renders it a gentle stimulus which can be borne in almost all cases, and adds much to its good effects; it is one of the simplest applications, and can be used over a greater surface than others of a more powerful nature. Dr. Duffin prefers an ointment composed of equal parts of diluted citrine ointment and tar ointment to any other topical remedy in the chronic cases, and states that it may be applied very extensively over the body without dreading its affecting the mouth, or producing any other of the effects peculiar to mercury. The patient is to be directed to remove the old ointment perfectly previously to laying on a fresh application, and to use for this purpose an alkaline lotion, made of two drachms of liquor potassæ to six ounces of water. The ointment adheres with great tenacity, and he "thus unconsciously submits the parts to a very perfect ablution and considerable friction, two agents of the utility of which no person can doubt in the case of lepra."

M. Biett, who thinks that ointments in general are of but little service, yet places confidence in one composed of the ioduret of sulphur and lard, twelve or fifteen grains of the former to the ounce of the latter. It is a very valuable remedy in recent lepra, occurring in a weakly individual who could not tolerate active internal medicines: it should be applied by a gentle friction to a few patches at a time, after a tepid bath: the skin's activity increases under its use; the circular elevations are reduced to its level, and the scales fall; and when the natural state is nearly restored in one part, new patches are to be attacked, until the resolution becomes complete.

Besides the Carron liniment mentioned before, the smearing of the patches with cream or with fresh butter, [or with cod-liver oil,] has been extolled as very efficacious in allaying irritation from the rigidity of the skin; and we can recommend with confidence the use of these emollients as excellent adjuncts to the general means of bleeding and purgatives, (which must be the chief reliance as we have mentioned before,) when the heat, itching, and stiffness give great annoyance.

A lotion that was held in much repute for detaching the scales when they adhere tenaciously, is a decoction of the stalks of dulcamara with some alkali: it is said even to bring the skin to a healthier condition. We should remark that benefit from these external applications, liniments, ointments, &c., is to be looked for chiefly when the disease is confined to the extremities, and shows little disposition to spread.

[In chronic cases, the ointment of iodide of mercury; or a liniment of the red iodide, or an ointment of the same; or the solution of iodide of mercury and arsenic, diluted with an equal quantity of water; or the tar ointment; or an ointment of creasote, or a liniment of the same; or an ointment of the sesqui-iodide of carbon, or of the iodide of ammonium, has been prescribed in the same cases as the iodide of sulphur. It has, also, been advised, that the patches should be touched with a liniment, composed of olive oil and rose-water, each an ounce, liquor potassæ, half an ounce; and, when they are small, they may be sometimes touched with advantage with strong acetic acid, or aromatic vinegar, or the mineral acids, when diluted: but, as elsewhere remarked, (*Practice of Medicine*, 2d edit. p. 137,) care, it need scarcely be said, must be had in the employment of these potent agents, and they never can be proper in the early and inflammatory stage. Recently, anthrakokali and fuligokali—simple and sulphuretted—have been recommended, both internally and externally; and Mr. E. Wilson (*On Diseases of the Skin*, Amer. edit. p. 360, Philad. 1843,) affirms, that he has employed fuligokali in several cases of lepra and psoriasis, and especially in psoriasis palmaris, and with better success than he had obtained by the usual remedies. The preparation and mode of administering these remedies are given elsewhere. (*New Remedies*, 4th edit. p. 57, and p. 321.)

Cantharides have likewise been prescribed externally. Dr. Davidson of Glasgow, (*Lond. and Edinb. Monthly Jour. of Med. Science*, Dec. 1841,) noted the comparative effect of iodide of sulphur, and the *Acetum Cantharidis* of the Edinburgh Pharmacopœia, in an inveterate case of several years' standing, in which a variety of remedies had been tried in vain. The iodide of sulphur was applied to the lower extremities, and the acetum cantharidis to the arms; and, from the result of his observations, he is satisfied that the latter had more power as a local agent. He found, however, the proportion of cantharides in the official formula too small, and therefore doubled it. Dr. Davidson recommends the following liniment, which is a modification of the *Emplastrum Cantharidis* of the Edinburgh Pharmacopœia, as superior to any preparation he has tried. It is sufficiently soft during warm weather to be applied with a brush; but requires to be heated when the temperature is low. (*Adipis, Ol Rapii, Cantharid*, pulv. āā ℥i.) In order to succeed with any of these vesicating agents, the skin should be previously softened, either by the warm bath, or by sponging with warm water.]

The most effectual means for combating lepra are, however, to be sought for in the internal medicines; and the experience of able observers has proved a great number of these to possess undeniable power.

The use of different medicated waters, as those of Harrowgate and Leamington in England, and of the different waters on the continent which contain sulphur, has been a long time established as very beneficial; we have of late had occasion to know of several cases that have been cured by

drinking the water of Lucan Spa which resembles the Harrowgate, but is not so strongly impregnated with sulphuretted hydrogen. This is a much better way of administering the sulphur internally than either the simple flores sulphuris, or in combination with antimony, the golden sulphuret of which was once a favourite remedy in cutaneous diseases. The mineral waters should, if possible, be drunk at the source, or at least be procured from it: as it is a fact that their imitations are not so efficacious as the waters of the springs.

The dulcamara has certainly properties which entitle it to notice. Dr. Crichton's testimony was very strong in its favour, and brought it much into use in the treatment of lepra. He states that out of twenty-three cases in which he employed it, only two resisted its action; two or three ounces of the decoction of the twigs and leaves were used by him thrice a-day; but we cannot help being inclined to attribute his success rather to the other means which he used, as the experience of other physicians who have used it still more extensively does not corroborate its virtues: it is still used, however, as an adjunct, in chronic cases.

Decoctions of the acrid stimulant plants, daphne mezereon, d. enidium, and of guaiacum, have been used with success in different instances. The compound decoction of sarsaparilla has also enjoyed much reputation, and may be recommended for its stimulant effects on the skin: its use should alternate with some of the more powerful remedies to be mentioned.

A remedy which at one time was extolled to an extravagant degree, and has fallen in late times into as undeserved disrepute, is the tar-water; but we are persuaded on the grounds of experience that it does possess real efficacy. A case has been communicated to us, which had been treated by some of the most eminent practitioners with the most powerful remedies: but no effect was produced on the disease till tar-water was tried by a physician whose experience of it led him to place much confidence in it; and under its use the patient got quite well. Half-a-pint of it should be drunk three times a-day. In the case alluded to the patient was made to walk rapidly until he began to perspire, and then to sit for a time in a warm room, and much importance was attached to this manner of exhibiting it. Pitch pills are also to be mentioned as a remedy to which experience bears a very satisfactory testimony; six or eight of them, each five grains, should be taken for a dose three times a day, and this will have to be increased by degrees according to circumstances.

Some English writers praise very highly the treatment by mercurial preparations; and in some cases minute doses of corrosive sublimate have proved of unquestionable utility, salivation by mercury being, however, seldom undertaken in the cure of lepra. The naïve relation which that respectable writer, Dr. Turner,* gives of its effects in two cases where he employed it, would answer for its history in most cases; and as a purgative, indeed, calomel will be very beneficial in occasional doses, no matter what plan of treatment be preferred; and in children particularly it is a very useful means.

We now come to speak of arsenic, a remedy that has been of late years much investigated as to its effects in squamous diseases. While some have found it to possess uncommon virtues, others have decried it as not only useless but dangerous. It is, without doubt, a very dangerous remedy in the hands of incautious practitioners, and will never prove useful if it be employed where circumstances contra-indicate it. But we must express our suspicion that where it has failed, it has been for want of discriminating between the states which are favourable to its action, and where its administration is improper. It is superfluous to say that its exhibition requires the most cautious attention on the part of the practitioner; and we are confident, that where it is judiciously employed, it is not only a safe but a very valuable remedy. It seems to be peculiarly applicable in those cases which are seldom benefited by other medicines — we mean those instances in which the lepra has lasted for several years, and has invaded nearly the whole skin, so that it has taken on such a diseased habit, that nothing less than the most powerful means will restore its original state. In cases which have not run on to a very chronic state, the other means will prove as effective, and probably should be tried before we should have recourse to the arsenic, although some able practitioners advocate its propriety in almost every case. In the inveterate cases, however, when all other means have failed to produce any salutary effect, its well-regulated exhibition has been frequently known to effect the dispersion of the disease.

Having determined on its use, we must watch its effects, and persevere so as to give it a fair trial. Fowler's solution of arsenic is the preparation most approved of. It is best to commence with the small dose of three drops, to be taken three times a day in a glass of water; or it may be deemed advisable to use the decoctions of dulcamara, mezereon, or of sarsaparilla as a vehicle, as Dr. Duffin recommends. The dose must not be raised beyond eight drops three times a day, or at the very highest ten. When it first affects the system, the pulse becomes quickened, smaller, and hard; and there arises a prickly soreness about the eyelids, accompanied by some puffy swelling, particularly of the lower one. The gastric symptoms which are the signals for suspending its exhibition, are, sickness of the stomach, griping pains all over the abdomen, headach and whitish tongue, with a peculiar taste in the mouth. When there comes on a pain in the chest, accompanied with anxiety of the præcordia, and a certain consciousness of serious constitutional disturbance, which is indicated by uncommon gravity of the countenance, the medicine has been either given in too large doses or continued too long. When the pain in the chest and any of the latter symptoms occur shortly after its commencement, it is probably a case which will not bear its administration at all, and other means should at once be substituted. It will generally be found that an impression has been made on the disease when its effects are recognised in the constitution, and often before this. At first the patches become

* A Treatise of Diseases incident to the Skin, by Daniel Turner, of the College of Physicians, London, 3d edit. 1726, p. 30, et seq.

less indolent, and a long-unaccustomed sensation of heat and activity is felt; the scales first clear off in the centre, (for in those inveterate cases the whole patch is overgrown with scales;) by degrees the circular eminences sink and clean; and thus a disease which had become engrafted on the habit for years, retires under the influence of this powerful medicine.

[Of late, a solution of arseniate of soda, the iodide of arsenic, and an iodide of arsenic and mercury, under the form of the liquor arsenici et hydrargyri iodidi, or "*Donovan's solution*," as it has been called from its proposer, have been used with advantage.]

Some of the favourable symptoms ought to show themselves by the time that the medicine has affected the pulse, or when the stiffness and puffiness are perceptible under the eyelids. If the skin do not discover its action when these characteristic signs appear, there is no necessity, —indeed it would be improper,—to continue its use. In others, nausea and loss of appetite, with some epigastric soreness and oppression, are the first signs of its operation; but we should not consider these latter symptoms as unequivocal reasons for laying aside its use altogether; a few days' intermission will often remove this gastric disorder, when a further trial may be made; and it has frequently happened that the good effects have begun to show themselves soon after its being resumed. But in deciding how far it may be pushed, the discretion and tact of the practitioner must guide him: we only wish to lay down as a principle that the arsenic is not so unsafe a means in judicious hands as it has been vulgarly thought; and that after its use is commenced, ill-grounded fears should not deprive the patient of the steady trial of a remedy which experience has proved to be so valuable. Dr. Duffin states that he has prescribed it in very near four hundred cases, and has never yet seen it do any mischief; and his testimony and that of M. Biett, (two gentlemen who have investigated its effects the most assiduously amongst modern observers,) agree that it is a most important remedy in this intractable discase.

The tincture of cantharides is another very energetic medicine in lepra. It was brought into notice by the eulogy of Mead, although it is nearly certain that it was against the tubercular elephantiasis that he employed it. (Medical Works of Richard Mead, M. D. Dublin, 1767; of the Leprosy, p. 455.) However that may be, it has been used ever since in the scaly disease, and it has been found of great effect, particularly of late years. It is applicable in the same invetcrate description of cases as the arsenic, and requires quite as much caution in its administration. Four or five drops three times a day should be the utmost dose for the first month of its use, and at the same time the patient should use demulcent drinks of gruel, barley-water, flax-seed tea, &c. When given at an improper stage, or in too large a dose, it is very prone to produce serious disturbances in the alimentary canal and the genito-urinary organs, so that when we perceive painful heat at the epigastrium, vomiting and purging, or stranguary and erections to follow its use, it must of course be intermitted; but unless these symptoms show an unusual degree of violence, it may be often advantageously resumed. By a cautious gradation of the dose, (very small at first,) and the use of the demulcent drinks, with an occasional dose of purgative medicine, those sinister consequences may in general be avoided.

In some remarks on the use of tincture of cantharides in hooping-cough by Dr. Graves, in the fourth number of the Dublin Journal of Medical and Chemical Science, Dr. G. states that it produces its good effects without causing urinary irritation when given in the formula recommended by Dr. Beatty, which we here subjoin:—R Tinct. cinchonæ compositæ ℥v; tinct. cantharidis; tinct. opii camphoræ, āā ℥ss. M. There is nothing in the other ingredients of this mixture which should preclude its trial in lepra; and it would be very desirable if this combination would allow of its free use, by averting its ill effects on the urinary organs. Bateman's disparaging notice of cantharides kept it out of use for some time; but its value has been confirmed by the experience of the Hôpital St. Louis, where it is esteemed as only second to arsenic in the chronic cases. Where either of these two remedies is found to create constitutional disorder forbidding its continuance, it may advantageously be replaced by the other: but we repeat, to derive good effects from either of them, the greatest care must be taken to use them in the proper stages; for if they be given whilst any activity of inflammatory action remains, instead of benefit we must only expect to aggravate the whole disease.

A course of purgatives is at the present time a favourite practice in the less severe cases of lepra with some French practitioners, who speak with much applause of the good effects of calomel, jalap, sulphate of magnesia, and of soda, aloes, &c. in its removal. We rather suspect that this may arise from the novel introduction of cathartics into their practice, and the reaction in their favour which naturally follows on the apprehension and horror they had of this valuable class of medicines up to a recent period. It is, doubtless, of the highest importance to keep the bowels free by the occasional use of laxatives; and for this purpose a few grains of calomel will be generally found the most suitable. Much purging, however, as far as our experience goes, is decidedly injurious, excepting probably in children, where we can have recourse to scarcely any other class of remedies, and where purgatives answer very safely and conveniently.

The external and internal means of treatment have been noticed separately for the sake of arrangement, but in practice they are almost always employed together; and, when judiciously combined, they mutually assist each other's action. The tepid bath may be used in almost every plan of treatment, and will be found a useful adjunct. In those cases which have not spread extensively nor lasted long, the treatment should be commenced by an abstraction of blood, which is to be repeated either generally or by leeches, whenever the inflammation shows any signs of having resumed an active state: at the same time the patient should use some one of the internal remedies, and probably daily the bath. With those it will be

often judged advisable to apply some of the unguents or lotions already mentioned, so as to conjoin the operation of the different classes of remedies; and it is in such cases that this combination is most effective. In the inveterate cases, our reliance must be placed in the steady use of the internal medicines. We can go no farther on these points; each particular case will doubtless present its peculiarities, which must be considered. Having adverted to the most approved principles, and mentioned the remedies whose virtues have been best confirmed by experience, it remains for the judgment of the practitioner to guide him in each particular instance in the application of the former, and the choice and conjunction of the latter.

[A thorough change of the diet and regimen to which the patient has been accustomed, as well as of all the influences surrounding him, by travelling, is advisable, whenever it is practicable; and this has been, perhaps, the main agency, when a visit to sulphurous springs has effected a cure in rebellious cases: at the same time, as before remarked, the sulphur has doubtless been an important adjunct.] J. Houghton.

LEUCORRHŒA, from λευκὸς, *albus*, and ῥέω, *fluo*. Properly, this name ought to be restricted to a *white vaginal discharge*, but every sort of discharge, not sanguineous or menstrual, has been at various times considered as leucorrhœa, whether mucous, serous, purulent, or of a mixed description.

Besides "*leucorrhœa*" and "*vaginal discharge*," this complaint has been called "*fluor albus*," "*fluor muliebris*," "*les fleurs blanches*," "*sexual weakness*," or "*a weakness*," and, vulgarly, "*the whites*." All these are more or less objectionable, and the one chosen for the title of this article as much so as any other; but it is one which is so well known and universal, that it can scarcely lead to error in practice, and is, therefore, the most convenient. It would, no doubt, be very useful in practice to discriminate between the different discharges, because very frequently their character will depend upon, and therefore be a guide to the knowledge of, the nature of the disease which produces them, or the particular part which has become disordered or disorganized. Sir Charles M. Clarke has classed the diseases of the female genital organs by the nature of the vaginal discharges which are peculiar to them; and although there are many serious objections to such a mode of classification, yet it proves how important it is to note their several and distinguishing peculiarities. Of the diseases to which females are liable, there is none more common than vaginal discharge, of one sort or another; it attends most of the uterine diseases, and it is extremely common as the result of either local or constitutional disturbance, or of general debility. It is looked upon by the patients themselves as the cause of ill health, or of the symptoms under which they may happen to labour; whereas, in the majority of instances, the discharge itself can only be considered as a symptom, the effect and result of local or general disorder. By practitioners in general, vaginal discharges have been carelessly attended to; there has been one common routine of treatment, without investigation; and it is only when the complaint has been obstinate, that at a later period more minute inquiry has been made, and more rational and scientific plans adopted. So many of the vaginal discharges depend upon uterine disorganization, or some alteration in the position of that organ, that it is advisable in every case, where possible, to make a minute examination *per vaginam*, so as to ascertain the exact condition. It is foreign to this article to enter upon the question of the numerous uterine diseases which give rise to vaginal discharges; we must here only consider idiopathic leucorrhœa, a simple vaginal discharge, unconnected with any alteration of structure.

The simplest form of leucorrhœa is a mere increase of the natural secretion from the mucous membrane of the vagina. As this membrane is continued to the interior of the uterus and the fallopian tubes, it is easy to suppose that now and then the lining of these organs may become affected, and the leucorrhœa have a more extensive seat. Frank has mentioned a case of unusual obstinacy, where, after death, the fallopian tubes were found to be the origin of the disorder; and numerous cases are on record, where, in prolapsus uteri, the leucorrhœal discharge was found to proceed from the os uteri itself. By many of the older writers, it was thought to be merely a variety of menstrual discharge, and hence the term "menstrua alba," &c. Hoffmann, Cullen, and others, considered that the discharge issued from the same vessels which secreted the menstrual fluid in their healthy condition. Dr. Jewel, in his recent work on this disease, states his impression to be, that it seldom issues from the uterine cavity, and proposes a test to ascertain that point in individual cases. Dr. Jewel assumes, that in the night-time, when in bed, the discharge from the interior of the uterus is suspended, which is not the case when it arises only from the vagina or the cervix uteri; and hence he advises that a piece of sponge be introduced into the vagina at bed-time, and if the uterus only is affected, the sponge will be withdrawn *dry* in the morning. The accuracy of this test must depend upon the assumption being correct.

[When it takes place from the uterus, it occurs, according to M. C. A. Tott, (Art. *Leucorrhœa*, in Most's *Encyclopäd. der gesammten Medicin. und Chirurgisch. Praxis*, Leipz., 1836,) more intermittently, and is accompanied by clots of blood and mucus, or by pain in the uterus. It, moreover, augments before and after each menstrual period, and is accompanied by more constitutional suffering.]

This is, however, by far the most common form of the complaint, which takes place from the vagina alone, or, perhaps, as this gentleman states, from the cervix uteri. There is an altered action of the mucous lining of the parts, and in what that particularly consists, depends the peculiarity of the cases. It has been by far too common to consider all such cases as arising from debility, local as well as constitutional, and hence the remedies have most frequently been merely strengthening. In general, we shall find great symptoms of debility accompanying long-continued leucorrhœa, but the debility is nearly always the consequence and not the cause of the disease. It is the acknowledged fact, that whenever the general health

has been broken down, and much constitutional weakness occasioned, local disorder is often the result, and such disorder may attack the uterine organs or vaginal passage, though it is not debility which affects them, but through debility a diseased action arises. This diseased action is sometimes acute inflammation; in others, and more commonly, sub-acute; whilst, in chronic cases of long standing, a relaxed condition of the secretion apparatus may take place from habit, as we see in the diseased discharges from other sources; this Dr. Dewees has called the "leucorrhœa of habit." Besides inflammatory action, a very large proportion of cases of leucorrhœa depend apparently upon irritation, different from inflammation, and yet easily running on into it—a state easily recognised, but difficult to be described. The irritation which excites leucorrhœa is very often remote from the vaginal membrane itself, so that, upon alleviating or removing the distant irritating cause, the complaint will cease.

The discharge of simple leucorrhœa is mucous—merely an increase of the natural moisture of the part; it becomes more abundant than in health, but retains its character of mucus, being clear, transparent, colourless, and glutinous to the touch. This rarely goes on to a great extent without being altered in its appearance, and much more watery. In general, this sort of discharge is accompanied with but moderate symptoms, is more gradual in its progress, and is unattended by pain; there is little or no inflammatory action present. [It has, indeed, in moderation, according to Dr. Simpson, (Tweedie's *Library of Medicine*, iii. 314,) been regarded as an indication of the general vigour and activity of the organs of generation.] In other cases, the discharge is whitish and opaque, becoming creamy when rubbed between the fingers, and rendering water turbid. This sort of discharge has been considered by Sir C. M. Clarke, and others, to depend chiefly on an inflamed condition of the cervix uteri; it is rarely abundant, but occasions much disorder of health, and local pain. A watery discharge, resembling serum, is a very common result of more acute inflammatory action in the mucous surface, and in general appears suddenly, as the effect of cold or any active excitement. It occasionally becomes very abundant, is attended with much local heat and soreness, and soon becomes puriform, or mixed with purulent matter, and sometimes with bloody streaks. When it is fetid, brown, or coming away in violent gushes, organic disease of the uterus is to be feared, the nature of which can only be detected by an examination per vaginam. Purulent discharge from inflammatory action may also take place from the vagina, independent of gonorrhœa from impure connection; and this may be said to form one variety of leucorrhœa, as, although it may often arise from organic disease of the uterus, it is not unfrequently met with in a perfectly healthy condition of that organ. Many will hesitate, perhaps, to class either the watery or the purulent discharge under the term leucorrhœa; but it is quite certain that all the above-mentioned discharges arise from the mucous surface of the vagina alone, without organic disease, and solely from a diseased condition of the natural secretion of the part.

Patients, in general, content themselves with stating the existence of a weakness; and too many medical men are satisfied with such a slight description, and neglect to inform themselves more accurately of the nature of the discharge.

The symptoms vary, as will be supposed, and there is a marked connection, in general, between the symptoms and the character of the discharge.

The mildest form of the disease is often of long standing before a practitioner is consulted: it is generally found that it has been preceded by what is called "delicate health." The countenance is pale and sallow; the frame weak; the pulse feeble, and easily quickened by the least exertion; the appetite impaired or capricious: the spirits are languid, and exercise is taken with difficulty; menstruation is either scanty, or too profuse; the digestion is disordered, and the bowels are irregular: there is pain in the back when the individual is fatigued, or when she remains long in the erect posture; but it is a pain of debility, relieved by rest, and not permanent. The discharge, which has been referred to weakness, is a disordered action of the mucous membrane, and is the effect of a state of indifferent health. The discharge, in these cases, is mucous only; is never very abundant, and is unattended by local pain, except in the back. It may easily be altered in character, and then the symptoms are also changed; as in such cases a very slight cause will increase the disordered local action.

The most acute form of leucorrhœa is most commonly the effect of cold, of metastatis, or of some local, irritating cause, and consists of a profuse watery or purulent discharge, accompanied with local soreness and pain. The vagina is hot, very tender to the touch; there is much fever, heat of skin, quickness of pulse: these symptoms being often preceded by a distinct rigor. When the discharge is more scanty and glairy, like the white of an egg, or creamy and opaque, the cervix uteri is considered to be principally affected, and may be felt by the finger to be hot and tumid, the pulsation of the minute arteries being easily distinguished. In these cases there is much pain of the back, extending round the hips and down the thighs, and, though relieved, not removed by the recumbent posture. This description of leucorrhœa may occur in the most debilitated or in the most healthy frames, and may be considered accidental. All of these forms may end in chronic leucorrhœa, where the discharge is more or less profuse and constant, mucous or purulent, or a mixture of both: it may become green and offensive, and yet be the result only of functional disorder. The quantity poured out is sometimes very abundant, even to the extent of a pint and a half in the twenty-four hours; it will then be expelled in gushes on any change of posture. There is in these cases a very relaxed vagina, often accompanied by prolapsus of the uterus: the mucous surface appears smooth and glossy, and has lost its natural rugæ; there is great emaciation and debility: the eyes are hollow; the face pale or chlorotic; the pulse feeble and rapid; the feet often anasareous; the respiration short and laboured, to which succeed palpitation of the heart, dragging pain in the back, inability to exertion, profuse nocturnal perspirations. Unless

remedial measures be successful, after a protracted scene of much general suffering, the patient dies, exhausted.

The causes of leucorrhœa are either those which induce inflammation of the parts or irritation, or which weaken the action of the secreting vessels, although by far too much stress was formerly laid upon the latter. Catching cold, as it is commonly termed, is a very frequent cause of the acute leucorrhœa; so also is metastasis of a discharge from some other part, though of a different character. The suppression of the menses, the repelling of milk in the breasts, the sudden checking of catarrh, and perhaps any sudden check to the perspiration, may be considered as causes of acute leucorrhœa: a severe labour, in which the vagina has been kept long upon the stretch, or where it has been injured by officious manual interference, or the use of instruments, will often cause the inflammatory leucorrhœa. Violent exercise, particularly dancing, or riding on horseback, the excessive use of venery, or pollution, have the same effect. Of the irritating causes, we may mention local displacements of the uterus, especially prolapsus; local tumours of the vagina or uterus, and, of the latter, polypus in particular; stone in the bladder, disease of the urethra, a loaded state of the rectum, the presence of hard scybala, or of ascarides. A pregnant uterus may act in this manner, and also by the increased local determination of blood which pregnancy produces. The impaction of a pessary, or of a piece of sponge introduced for other purposes into the vagina, has sometimes been the unsuspected cause of a long-standing leucorrhœa. [Hence, it is all-important, in obstinate cases, to make an examination *per vaginam*.] Of the debilitating causes, may be mentioned frequent child-bearing, repeated abortions, profuse menstruation, and, in general, all the usual tendencies to disordered health, such as hot rooms, luxurious habits, indolence, poverty of living, protracted lactation, over-exertion, &c.

Treatment.—It is in this point that the greatest errors have prevailed, from the disposition to follow carelessly an established routine. Astringent tonics—bark and acid for instance, are prescribed in the majority of cases, and perhaps an astringent injection, which would aggravate many of the forms of leucorrhœa we have been mentioning. The plan of treatment ought to be regulated solely by the character of the complaint. It must be recollected that it is not always safe to check suddenly a long-standing leucorrhœa, if profuse. Many instances are on record of mischief resulting from such a course, and the following case is a striking illustration. We were consulted by a soldier's widow, several years ago, for a complete prolapsus of the uterus, produced by violent exertion during the retreat from Corunna, within a few days of her confinement, and which had never been reduced. There was profuse semi-purulent discharge from the inverted vagina. After some difficulty, the uterus was replaced within the pelvis, and a pessary worn, consisting of sponge soaked in an astringent lotion. The discharge from the vagina ceased; and in twenty-four hours a quantity of muco-purulent fluid began to be copiously expectorated from the bronchial membrane, which amounted, after a few days, to nearly three pints in the twenty-four hours: and, in less than a fortnight from the replacement of the uterus, the patient sank from exhaustion.

In the leucorrhœa from constitutional debility or disordered health, of the first class described, the usual remedies for restoring the vigour of the frame are required. Tonics of every description are admissible, according to the circumstances of the case; but those containing or combined with the mineral acids have most efficacy. The vegetable bitters, or the sulphate of quinine or the bark itself, may be given three times a-day, combined with from ten to twenty drops of the diluted sulphuric acid, or double that quantity of the old vitriolic elixir. From one to two grains of the sulphate of zinc, or any of the preparations of iron, will often agree exceedingly well, and as the health improves, the discharge becomes less and less abundant; the diet should be nourishing, the air good and occasionally changed. Besides these remedies, the shower-bath or cold bathing may be used, and especially hip-bathing, or sponging the back and loins freely with cold vinegar and water or salt water. Local remedies are rarely required in these milder cases. In the acute form of the complaint, it is often necessary to apply leeches to the neighbourhood, to the groins, labia, or back; and if the cervix uteri is particularly affected, to the os uteri itself, by means of a proper tube. This is much more easily effected than is supposed, and the liability of the leech remaining at the lower end of the tube instead of crawling up to fasten upon the uterus, may be prevented by inserting a piston to push the leech higher up the tube. Bleeding from the arm is rarely necessary, though in plethoric habits it may now and then be desirable. A low diet, perfect rest, and antiphlogistic general treatment are necessary; the bowels should be kept fairly open with saline purgatives or castor oil, avoiding aloes, scammony, or others of a drastic character; warm hip-bathing is very useful, and injections into the vagina of warm water, decoction of poppies, or solutions of the super-acetate of lead. Dr. Jewel advises, very confidently, weak solutions of the nitrate of silver as injections, in the proportion of one to three grains of the salt to an ounce of distilled water, or even the application of the caustic itself to the cervix uteri. We doubt, however, whether this treatment is applicable to this very acute form of the disease.

When more chronic, when there may be said to be subacute inflammation only present, or perhaps only irritation, the general health must be attended to, according to the nature of the general symptoms; but in such cases the greatest benefit will arise from local treatment, or from remedies more especially directed to the local mischief. It is this form of the disease which is most obstinate, and for which it is advantageous to possess a variety of remedial measures. Of the internal medicines which have been found serviceable, the balsams, particularly the copaiba, have been mentioned; but their efficacy is not nearly so marked as in the gleet or gonorrhœa of the male: the cubebs has also much about the same remedial powers. The cicuta has been found of service by some practitioners. The tincture of cantharides has been perhaps more successful, pushed to

as large a dose as can be borne without producing irritation of the bladder. Astringent medicines are also found occasionally serviceable, particularly the mineral acids with the infusion of roses and alum; the latter may be given in doses of from five to twenty grains three times a-day. The acetate of lead has been often successful, catechu, kino, uva ursi, powder of galls, which may be given in large doses. At the Lock Hospital, Mr. R. B. Walker is in the habit of giving ten to twenty grains of the latter in decoction of tormentilla. Dr. Copland recommends small doses of the sulphate of copper. Emetics are said to have been of use, but perhaps in the more acute form of the complaint. The local remedies, however, are most to be depended upon in these cases, and may be applied freely and several times a-day, either by means of the female syringe, or of a piece of sponge or lint introduced carefully into the vagina, and occasionally withdrawn for a fresh supply of lotion. Most of the female syringes are too small, and produce irritation by the frequent necessity for withdrawing the pipe for the purpose of refilling the instrument. The writer has been in the habit of obviating the inconvenience by a gum-elastic tube of three to four inches in length, and about half an inch in diameter, perforated with several holes at the apex, which is rounded off, and the tube made to fit to the stomach or lavement pumps, which are now so common: in this way any quantity of fluid may be injected into the vagina without withdrawing the tube. The applications may be classed into the irritating, the sedative, and the simple astringent; and as a general rule, it may be stated that the first are most applicable to the chronic states of subacute inflammation, rousing the vessels into a more healthy action. These consist of solutions of nitrate of silver (as just mentioned), of the sulphate of copper, of oxymuriate of mercury, &c.; inunctions of mercurial ointment, fumigations of cinnabar, or the local application of copaiba or turpentine. Dr. Jewel limits his lotions to the strength of three grains to an ounce of water, preferring the application of the lunar caustic itself to a stronger solution; but at the Lock Hospital, solutions of the strength of half a drachm, or even two scruples to the ounce, are not unfrequently employed. [Dr. Huston, of Philadelphia, has seen more advantage from injections of the oil of turpentine, than from any other: *Ol. Tereb.* f.ʒi. *mucilag. Acaciæ*, aquæ āā f.ʒiss.] The sedative injections consist of decoction of poppies, of solutions of opium or belladonna, and of the superacetate of lead, the last being by far the most efficacious. The writer is in the habit of using the common Goulard's extract in the proportion of two or three drachms to the pint of distilled or rain water, warm or cold according to the sensations of the patient, and he prefers as much as half a pint to a pint to be used at a time, three or four times a day. The sedative lotions are most serviceable where there is an acrid discharge, with heat and excoriation, or where there is much inflammatory action with local pain. In some severe cases he has seen benefit from introducing a piece of lint soaked in a liniment consisting of equal parts of Goulard's extract, Battley's laudanum, and mucilage. The astringent injections are applicable to the cases which appear to be attended by great relaxation of the vagina and its mucous membrane, with chronic discharge of a muco-purulent or simply thin mucous character. All the vegetable astringents are then occasionally serviceable, as well as the mineral. Alum, the sulphate of zinc, iron, or copper; the acetate of zinc; decoctions or infusions of oak-bark, galls, green tea, kino, catechu, rose-leaves, &c., may be alternately used, or some may be combined together; but a great deal depends upon their being used freely and frequently. In using astringent injections, particularly alum, it is advisable to wash out the vagina directly afterwards with cold water, as the discharge will sometimes become coagulated, and, remaining in the vagina, produce irritation and an increase of the symptoms. Leucorrhœa has been said now and then to be owing to want of cleanliness, and no doubt this may cause it, but it would be difficult to prove that no other cause existed. The remedy is obvious.

When there is reason to believe that the leucorrhœa depends upon a loaded state of the rectum or the presence of ascarides, a soap or a turpentine clyster will readily remove both cause and effect. In the leucorrhœa of pregnancy, more caution is to be observed. In the early months it is desirable to check it, as an excess of it will be very likely to bring on abortion; but it must be done gradually, and the lead injections are the safest. Where the discharge arises principally from the uterus, conception rarely takes place; and when it has occurred, the ovum is easily separated by the slightest causes, so that extreme quiet is always necessary for the first few weeks. In the latter months of pregnancy, leucorrhœa may be looked upon rather as a relief, unless excessive; the pressure of the gravid uterus and the greater determination of blood to the neighbourhood frequently producing symptoms of heat, weight, and discomfort, which are alleviated by the escape of the discharge. Rest and cooling laxatives, with a spare diet, are generally all that will be required.

[Uterine leucorrhœa is by no means as much benefited by astringent injections as the vaginal. It would appear, indeed, that, at times, they cause great irritation, and an aggravation of the local distress. The acute form requires cupping on the loins, with the hip-bath, and warm emollient injections into the vagina and rectum; and, after the active stage has passed away—or at any time, in the chronic form—counter-irritants may be applied to the sacrum, as the ointment of tartrate of antimony and potassa, croton oil, or dry cups. If a blister be applied, it ought not to be kept on too long, and its surface should be covered with tissue-paper, to prevent, if possible, the absorption of the flies or of their active principle. The same internal remedies, directed to the special pathological condition of the frame, are needed as in vaginal leucorrhœa. Of late, it has been affirmed that ergot has succeeded where other remedies had failed, in both the uterine and vaginal variety. It may be given in the dose of five grains three times a day.]

Very young children are liable to leucorrhœa. It occasionally occurs in infants shortly after birth; in these cases it is more or less purulent, and at-

tended by a redness and tumefaction of the orifice of the vagina. It is very apt to occur also during dentition, and not only when the first set of teeth are in progress, but at the time of the second set, and even when the dentes sapientiæ are irritating the system at a more mature age. Young girls are also sometimes affected with leucorrhœa, attended with debility, disordered health, and pain in the back. This usually arises from intestinal irritation or from gravel, though probably the latter may be equally the effect of the visceral disorder. It must be borne in mind that the appearances above described are not unfrequently the effects of improper habits. The curative measures are simple; the portion of the vagina affected is usually very limited, generally near the external orifice, so that the Goulard lotion is readily and effectually applied. Alkalies and gentle purgatives with a mild diet and rest, will in most cases be sufficient to remove the complaint. An epidemic vaginal catarrh has occasionally existed, as mentioned by Professor Capuron to have prevailed in Paris. It has also been observed in this country among children, but attended by much local inflammation and constitutional disturbance of a typhoid character, and which, unless treated very early, has ended in ulceration, sloughing of the pudenda, and death. These cases have been described by Dr. Percival of Manchester, as having occurred there in 1791. Again, in 1815, the attention of the profession was called to them by Mr. Kinder Wood, who had then seen twelve of them, all occurring at Oldham, or the immediate neighbourhood of Manchester. Dr. Mackintosh, of Edinburgh, has described four cases, of which two followed immediately after measles; and it is not uncommon to find a milder sort of leucorrhœa making its appearance after the subsidence of that eruptive disease. Except those mentioned by Dr. Mackintosh, it is curious that nearly all the others have been noticed in the neighbourhood of Manchester; for Dr. Ferriar, who practised there also, states, in his "Medical Histories and Reflections," that he had "met with several instances" of a similar nature. The cases related by Dr. Percival are important on another ground, as the first instance which fell under his notice led to the committal of a youth for a supposed rape, the appearances on the pudenda of the child having led to the suspicion that violence had been committed. The rapid occurrence of several similar cases alone saved the youth from trial and probably execution. The recollection of such facts is of real consequence when an opinion is required upon supposed instances of defloration.

There is one material point connected with cases of leucorrhœa, and especially those where the discharge is purulent or of an acrid character. In such instances it is well known that sexual intercourse will often bring on a train of symptoms very much resembling gonorrhœa in the male. This, when occurring between husband and wife, has often led to much domestic unhappiness, from the supposition of one party or the other having contracted gonorrhœa from impure connection. It is important to be able to distinguish between gonorrhœa and common leucorrhœa to remove or confirm the suspicions, but it is very doubtful whether any very accurate diagnosis can be formed. It has been stated that in a recent gonorrhœa there is ardor urinæ, which does not accompany leucorrhœa, unless unusually acrid. But how are we to distinguish in a case of this unusually acrid leucorrhœa, or where a gonorrhœa is not recent? The redness and tumefaction of the labia, nymphæ, &c. only can be seen in a recent gonorrhœa, and they may be seen in severe cases of leucorrhœa, particularly in those following local irritation, or possessing more acute inflammatory action. One other test is mentioned by authors, that in leucorrhœa the discharge ceases during menstruation, but does not in gonorrhœa. This, however, is denied by other authors, and, as Dr. Jewel observes, "this is a point which cannot easily be decided, as from the colour of the menstrual secretion, that of the leucorrhœal or gonorrhœal must necessarily be in a great measure obliterated." From what has been stated, it is quite evident that it is extremely difficult to distinguish between the two diseases, and particularly when we recollect how ready the party in fault will be to conceal or distort the facts. In all such cases it becomes the duty of the medical man to give his assistance not only in curing the disease, but in preserving domestic harmony.

C. Locock.

LICHEN, λειχήν. The cutaneous affection known formerly under this term was supposed to be, with several others, a mere modification or symptom of the lepra Græcorum (about which disease we have seen what confusion reigned—see Lepra); and we find that this improper notion was still held by writers at the beginning of the last century. It was also erroneously represented to be synonymous with impetigo. All this originated in its not being quite clear what was intended by the term λειχὴν in the Hippocratic writings, and in a misconception of Celsus. The latter describes under the name of *papulæ*, a form of cutaneous eruption which the best authorities consider to be the same as the λειχὴν of Hippocrates, and it is quite evident that he means a perfectly different disease by the term impetigo. Able commentators assert that the λειχῆνες of Hippocrates (Aphorism. sect. iii. aph. 20,) signify what they denominate "pustulæ siccæ,"—an expression which accords in sense with the papulæ of Celsus, and the same term (or pimple) which is adopted in modern nomenclature from the Roman author. Since the time of Willan, indeed, his application of lichen has been in universal acceptation, and it now always signifies an eruption of small, solid, reddish papulæ, which terminate with a scurf, and are very liable to recur.

The papulæ of lichen usually occur in adults, and are often connected with internal disorder, but not so exclusively as to be admitted into the definition: they are accompanied always with more or less pruritus, and are situated on the arms, face, or legs, and sometimes are developed all over the body.

But the closer description of the disease and its course requires that we notice its varieties; and here we may remark that we differ from those authors who deny the utility of entering into more minute distinctions than are necessary merely to denote the generic relations of the cutaneous affections. It is true that multiplying terms *use-*

lessly would only tend to embarrass the student of those diseases; but it is equally certain that classifying phenomena according to the various relations of form, colour, situation, extent, and other conditions, and thereby establishing *real* varieties, not only is highly conducive to the advancement of the pathology of those affections, but very much facilitates the attainment of a practical acquaintance with them. It appears to us to be as indispensable to the study as it is to the description of them, to have specified varieties fixed in the mind by distinctive appellations; and we confidently affirm that students who were really interested in acquiring a knowledge of skin-diseases have ever found material aid from the division into species accomplished by Willan. Their imperfections are, of course, manifold, but it is a proof of their utility to observe that every systematic writer, whatever his sentiments be with regard to them, whether he admire them or call for their abrogation, is obliged to notice them. The fact is, that they burden the memory of those only who make the vain endeavour to learn skin-diseases by books, while they assist in a very efficacious and pleasing manner the labours of the patient observer of nature.

The principal species, or rather varieties, of this affection are the following.

1. *Lichen Simplex.*—This is the species most commonly met with. It consists of small red papulæ, more or less elevated and acuminated, which contain no fluid of any kind, and are quite opaque and solid. It mostly commences on the face and the back of the hands, and, when more generally extended, it affects in preference the posterior and exterior parts of the arms and thighs. It may be stated generally, that it occurs most frequently in those parts of the skin which are most delicate and exposed to external influences. The eruption of papulæ is accompanied with a tingling formication, which is very disagreeable, particularly during the night, or when the person becomes heated by exercise or otherwise.

This variety is either acute or chronic in its course and character, but much oftener the latter.

In the *acute* form the papulæ are very red, and the inflammatory action accompanied with much heat and itching. After three or four days their redness diminishes, and having thrown off a minute furfuraceous scurf, they disappear. They are, however, at the same time followed by others. In about a fortnight after four or five successive eruptions, it generally subsides altogether. This acute form of the affection mostly occurs on the face and trunk.

The *chronic* form is generally situated on the limbs, and prefers, as before mentioned, the posterior and exterior surface of these. The papulæ have scarcely any inflammatory character, and the pruritus with which their manifestation is preceded or accompanied gives but trifling annoyance.—While some are sufficiently red, it requires that we pass the fingers over the great majority which stud the surface to distinguish them, so little do they differ from the rest of the skin in colour. The papulæ remain from a week to a fortnight, and leave the branny desquamation behind on waning; but the duration of the affection in the chronic form is quite indefinite, as fresh successive crops of pimples protract it often to many months. It manifests its tenacity sometimes by breaking out in a different part of the body after disappearing from its original situation, and it is liable to recur from the slightest cause, when the patient thinks that he is at length clear of it; such as changes of weather, errors in diet, or unusual exercise.

2. *Lichen circumscriptus.*—This variety is distinguished by a marked peculiarity of form. The papulæ, which in the former species are scattered without order, assume in this a circular arrangement. At the first view nothing may be observed beyond a ring of red papulæ, but on closer inspection these are found to inclose areas covered with a minute farinaceous desquamation, which is detached from small papular eminences beneath. The external papulæ alone manifest any inflammatory redness, or if those inside the circles differ from the rest of the skin in colour, it is only by a light pinkish hue. The circumferences of these circles, at first so small that the papulæ lie clustered in contact, soon spread by new eruptions, while the old borders fall into the desquamating centres. They seldom enlarge beyond the size of a shilling, and when the eruption is extensive, they mingle their circumferences, yet not so intimately but that it is always easy to recognise their circular form. This variety occurs as frequently on the trunk and face as on the extremities. From its tendency to spread and to propagate by forming new patches, it is not to be speedily eradicated. We have observed it occurring most frequently in early youth: it is called by boys at school *wildfire.*

3. *Lichen pilaris.*—This differs from the *lichen simplex* probably in no pathological character save that the papulæ are developed at the root of the hairs, which perforate their centres. This variety is remarked to be more chronic in its duration, and to be accompanied with greater irritability of the skin, than any of the preceding. Bateman's observation accounts for this: he states that it is often connected with derangement of the digestive organs, produced by ardent spirits.

4. *Lichen lividus.*—This is a kind which almost always occurs in persons with constitutions broken up by misery and privation. It consists in dark violet pimples scattered here and there on the legs and thighs; they are flat and broad, and are generally mixed with specks, which differ in nothing from purpura, to which disease this form of lichen is evidently allied. It is not so rare as some authors assert, but it is of little importance in a medical point of view, as in most cases its cure is to be promoted rather by the charity than the professional services of the physician.

5. *Lichen agrius.*—This is the severest form of this disease, as its name implies. (Ἀγριὸς, *ferus, agrestis.*) The papulæ are smaller than in the lichen simplex; they occur in congregated masses, and are very numerous. Their colour is deep red, and the skin where they arise is affected with a vivid erythematous inflammation, which spreads between them and beyond them. The heat or pruritus which accompanies their eruption is of the most violent character, and often deprives the patient, night after night, of rest: he cannot avoid scratching the pimples, and often employs a hard brush for this purpose. This pro-

ceeding, although rendered irresistible by the intolerable burning and itching, only tends to make matters worse; it aggravates the inflammation, and encourages the development of new patches. Besides this, where the papulæ become forcibly abraded, small ulcerations ensue, and a liquid oozes from them which forms thin crusts or scaly concretions. In some rare cases the affection appears to be relieved by the discharge, and having soon thrown off the soft incrustation which the latter formed, the cutaneous inflammation and its effects subside. The general course of the disease is, however, very different; painful exacerbations and new eruptions take place for many weeks; and at length it falls into a chronic condition, in which the inflammation nearly ceases, and the pruritus becomes much mitigated. In this condition it remains for an indefinite period, the serous secretion being checked, and the scaly crusts becoming dry, and diminished to a farinaceous exfoliation. After a severe attack of this affection the skin remains for a long time thickened and rough, and retains a morbid sensibility, which persists for a considerable space.

This aggravated form of lichen is sometimes produced from the lichen simplex by causes, general or local, which determine a higher inflammatory action. In such a case the inconsiderable itching which accompanied the pimples of the original species is changed into a burning pruritus; the papulæ become in some places apparently confluent, and surrounded with a deep red inflammatory areola; and thus it proceeds in the course described. It more generally, however, commences as a distinct form, putting on its characteristic severity from the very beginning. In that state where the lymphy fluid which exudes from the abraded and ulcerated papulæ concretes into crusts, it approaches very nearly to the character of eczema. If it persist without showing any tendency to heal, after some time a purulent secretion forms, and may become, as Celsus remarked, really converted into impetigo.

The situation of this species is uncertain. It occurs with about equal frequency on the face, trunk, and extremities. It is not peculiar to any period of life, as it happens at all times from childhood to old age; but it appears to be more frequently and easily excited in those vitiated habits of body produced by addiction to spirituous liquors. This is more particularly the case among the poor, who, in addition to the injury done by the drinking itself to their organization, deprive themselves of a wholesome nutrition to indulge this miserable propensity. It is always preceded or accompanied by some fever and gastric derangement, sometimes of a serious nature; such as headach, nausea, vomiting, and loss of appetite, also general soreness and pains. Internal disorder is also very apt to occur if the eruption be repelled by the unseasonable application of cold.

6. *Lichen urticatus.*—This is a variety which well deserves to be separately specified. It consists of an eruption of large red papulæ, like the wheals produced by the stinging of nettles. They are found on the neck and arms of young persons, and those of a delicate skin, in spring and summer. It disappears with a slight exfoliation after a short time, and recurs again generally several times before it is finally removed. The pruritus which accompanies it is not of the acrimonious character of the last species, but it gives considerable annoyance, particularly at night, when it also is accompanied by a slight feverish access.

M. Biett describes a variety distinguished from any other by the papulæ displaying a spiral or circularly twisting arrangement. He has given it the name of *lichen gyratus.* (*Cazenave et Schedel,* Maladies de la Peau d'après M. Biett, p. 269.)

Lichen tropicus is a species which appears to differ in no respect from the other varieties except in the rapidity of its invasion, and the greater intensity of the itching, which are caused by the high activity of the cutaneous action, and the general exaltation of sensibility which the solar heat gives rise to in the torrid zone. It is appropriately called the "prickly heat" in the tropical countries. "The sensations arising from it," says Dr. James Johnson, "are perfectly indescribable, being compounded of pricking, itching, tingling, and many other feelings." It is usually, but not invariably, accompanied by an eruption of vivid red pimples, not larger in general than a pin's head, which spread over the breast, arms, thighs, neck, and occasionally along the forehead, close to the hair. This eruption often disappears in a great measure when the patient is sitting quiet and the skin is cool; but no sooner does he use any exercise that brings out perspiration, or swallow any warm or stimulating fluid, such as tea, soup, or wine, than the pimples become elevated, and but too sensibly felt. As would be anticipated, the new comers are much more liable to this unpleasant affection than natives or long residents; for the susceptibility of the skin is greater, while the contrast between the cold and hot climate is still sensibly present; but even natives are not exempt from it. The fears which Hillary and Mosely express about dangers accruing to the patient from repulsion of the eruption by cold bathing are ungrounded; but Dr. Johnson states "that the cold bath rather aggravated than appeased the eruption and tingling, especially during the glow which succeeded the immersion." "The only means," says he, "which I ever saw productive of any good effect till the constitution got assimilated to the climate, were light clothing, temperance in eating and drinking, avoiding all exercise in the heat of the day, open bowels, and, last not least, a determined resolution to resist, with stoical apathy, (the temptation to scratch,) its first attacks." Mr. Plumbe remarks with justice, "that the prickly heat is not confined to the climates from which it derives its name. In fact, the lichen *urticatus* occasionally occurs in these countries with an intensity of itching and tingling that must be quite as tormenting as the tropical affection. The writer knew a person who for several successive nights was obliged to jump out of bed from the sudden supervention of an intolerable heat and itching, produced by an eruption of this nature. The pimples which arose on the head in particular produced such irritation, that the patient felt as if they would make him mad. After remaining in the cool air for a while, and taking a draught of water, they subsided, and allowed him to go to sleep at an advanced period of the night, leaving him quite free till the next night. It is often

brought on in spring and autumn, in young persons, by violent exercise, and it is a penalty not unfrequently paid for dancing in these seasons. Mr. Plumbe mentions a case where a public performer was obliged to forego this manner of obtaining a livelihood from the severity of its attacks. (Practical Treatise on Diseases of the Skin, p. 251, third edition, 1832.)

Diagnosis.—To some of the foregoing varieties may be referred every example of lichen; but these papular eruptions are so manifold, and pass so readily into one another, that it may be difficult to assign its proper place to individual cases: this, it will be conceived, is not of essential importance. Although we have adopted this division into species because we are convinced of its convenience and exactness, and think that it tends to forward the study of cutaneous pathology, yet it is not intended to impose a notion on the student that we derive at present much assistance from them in the treatment. Their diversity consists, at least chiefly, in the degree of inflammatory action, and is much influenced by the previous constitution of the person, their circumstances and habits, local relations, &c. The causes which produce them afford, also, a proof of their agreement. They may be comprised under two general heads:—1st. Heat, either of the atmosphere or artificial. This is a common source of them, from the slightest summer rash (lichen simplex) to the prickly heat. Blacksmiths and glasshousemen are very constantly affected by some form of it, from the heat of their furnace and forge. 2d. Derangement of the digestive organs, either from improper diet and spirituous liquors in excess, or defective and unwholesome aliment. To this head are often to be traced cases of lichen agrius, lichen urticatus, and to the latter cause particularly the lividus.

An accurate diagnosis of lichen is not always easily made. It is of considerable importance in practice, however, to be able to distinguish it, more indeed for the sake of determining what it is not, than for establishing its own identity. We must be particularly cautious not to confound it with any of the exanthematous eruptions, with measles or scarlatina for instance; but it is only necessary to point out here the possibility of this mistake: if the description of the varieties above given be fixed in the mind, it cannot occur.

From scabies, prurigo, and eczema, the lichen simplex is not so easily distinguished. We will observe, in drawing the distinction, that scabies comes out in vesicles which discharge a fluid on breaking, that it occupies the intervals, between the fingers, and the flexures of the wrist and finger phalanges; on the other hand the solid red papulæ of lichen are very different from the transparent vesicle of scabies; they are situated, as we have seen, on the exterior parts of the arms and thighs; and if they appear on the hands, where scabies almost universally begins, they occupy the dorsal surface, and do not affect the joints or the intervals of the fingers. The contagion of scabies would settle the question if this were ascertained, but this is never the case where there is a doubt as to the diagnosis. It is, in fact, to procure information as to the contagious nature of the eruption under consideration that diagnostic marks are valuable between scabies and lichen, in order that proper precautions may be taken, in case it be the former, to prevent it spreading. Lorry sums up the difference between them with conciseness and accuracy. "Primo a scabie differunt, quod papulæ illæ (lichenis scil.) vulgo magis confertæ sint et clatiores; 2°. quod rubicundæ magis et minus aridæ sint; 3°. quod sanatis febribus superveniant; 4°. quod latiores sint, et sæpius recidivam patiantur quam vera et legitima scabies; 5°. quod in furfur abeant notabile; 6°. demum quod remediis sanentur a scabiei curatione alienis." (Bateman's Synopsis, *note*, p. 8.)

The papular nature of prurigo comes nearer the external character of lichen simplex, but the pimples of the former are larger, much more separated, and seldom differing in colour from the surrounding skin; they are not acuminated as in lichen, and are covered generally with a speck of dark blood: this is produced by abrasion in scratching, the pruritus being of a peculiarly acrimonious nature; whereas in lichen simplex it is comparatively mild. Lichen may simulate eczema so closely as to require much tact and consideration to decide between them. When the eruption of lichen simplex is very vivid, there often appear, here and there, some vesicles; and when with this occurrence it happens that the patient abrades the summits of the papulæ, the excoriations give out a fluid which concretes and forms soft crusts; in this state many of the features of eczema are present. On inquiry it will be ascertained that at first the eruption was entirely papular, and that the few stray vesicles are merely adventitious. They generally come out after the excoriations have been made, and in their immediate neighbourhood.

The lichen agrius is still more difficult to distinguish from eczema. We must rely on the history of the eruption, and the character of the elevation of the skin, which is vesicular in the latter case, and papular in the former. This can generally be determined by examination after the crust which covers it is removed. Besides this, the irritation which the real eczema causes is strongly contrasted with the burning itching of the papular eruption; but this distinction may fail after a long duration of the latter disease, and the others become so confounded, that it is often impossible to distinguish between them.

It has been already stated that lichen agrius sometimes takes the characters of impetigo, but the reverse never takes place; the latter ought never to be mistaken for the former. The small psydracious pustules of impetigo are manifest from the beginning, and the coarse crusts which form on their breaking are different from the thin layer which the excoriations of lichen furnish.

When lichen agrius subsides into a very chronic state with a tendency towards cure it is often so much overlaid with furfuraceous exfoliation as to be taken for a scaly disease. Some authors, indeed, assert that it is not uncommon for it and for the lichen simplex to be converted into psoriasis. The writer has lately seen a gentleman who had on the arms and chest an eruption of lichen simplex, which in the axillæ and the folds of the buttock was changed in character so as to resemble ptyriasis more than any other cutaneous affection.

Lichen circumscriptus has often been mistaken for herpes circinnatus; we have lately seen a skilful observer make this oversight. It is to be borne in mind that the circular patches of the papular eruption are smaller, and show no vestiges of vesicles or their remains, which are always discernible on closely inspecting the rings of herpes circinnatus. Moreover the central space of the latter is quite untouched, but in the lichen the papulæ are still recognised, paler than the external circle, and overlaid with the farinaceous scurf. It is proper to remark that the psoriasis guttata has been also mistaken for lichen circumscriptus.

The difference between lichen urticatus and urticaria will be ever easily recognised by any one that has seen both affections. Besides the exanthematous character of the latter, the form is quite distinct. The papulæ in the lichen are large, elevated, distinct, and are more or less permanent. The wheals of nettle-rash are confluent, flat, and scarcely ever remain beyond a few hours at a time. This lichen may also be mistaken for the venereal eruption called by some authors lichen syphiliticus. The latter disease is marked by its coppery hue; besides it is destitute of the pruritus which accompanies all proper lichens, and it is more steadily persistent than lichen urticatus. Again, it is seldom found alone, almost invariably accompanied by some of the other attendants on secondary syphilis.

Prognosis.—In none of its varieties can lichen be considered as a dangerous disease, and in the less scarce forms almost the only importance that attaches to its presence is the troublesome itching which the pimples occasion. When it arises from merely local or temporary causes, such as the directly irritating action of the spring or summer heat, it is of little consequence and of short duration; but if its origin be more deeply seated in the constitution, if it be liable to frequent recurrence and exacerbation, it leads to more unpleasant consequences. It is in such instances that it gives rise, after a long duration, to a thickened rugous state of the skin, which completely obstructs its function of exhalation. At other times, as we have before stated, under similar circumstances it becomes complicated with eczema and impetigo, and, according to Biett, sometimes degenerates into ecthyma. The lichen agrius, as it is the most severe of all the varieties, so is it also the most difficult of cure; when situated in the face, it more particularly resists with uncommon obstinacy all therapeutic means. It may be stated as a general rule, that this and the other varieties are difficult of removal in proportion as they are of long duration.

Treatment.—In the lighter forms of this eruption, the treatment is simple. It demands, indeed, but little interference from the physician. His services here are seldom required further than in making an accurate diagnosis, tracing the eruption to its true cause, and laying down principles of treatment. As they generally occur in warm weather, and depend more or less on it, the individual should keep the house for some time, and thus abstract himself from the direct heat of the sun and from exercise, which last is one of the most common exciting causes of it. It will be useful to employ every day towards evening the tepid bath. Some even prefer the cold bath; the warm bath is too stimulating to the skin. To coincide with these cooling means, it will be requisite to adopt a diet in which the allowance of animal food is diminished. It will rarely be necessary to inhibit it altogether, but the greater proportion that vegetable and farinaceous matters make in the meals the better. Wine and spirituous drinks should be laid aside, but there is no objection to a moderate quantity of table-beer. As to medicines, it will be sufficient to give a saline laxative occasionally, so as to keep the bowels open: sometimes it will be judicious to use a few grains of calomel or blue pill for this purpose; potions of lemonade are much used in France. Bateman extols the use of dilute sulphuric acid where a grateful tonic is called for. For allaying the itching, various topical applications have been used. Mucilaginous decoctions, as that of marshmallows, are said to have a soothing effect. A lotion with two drachms of prussic acid to a pint of water has been also recommended highly. We believe that one of the best applications for this purpose is milk of almonds, in the composition of which a few bitter almonds have been mixed; with this the skin should be gently moistened three times a-day, or whenever the pruritus become troublesome.

In some of the acute cases where a good deal of fever accompanies the eruption, or where much sympathy is evinced in the digestive organs by vomiting, loss of appetite, or pain in the head, it will be highly advisable to take away some blood from the arm, and to pursue a more decidedly antiphlogistic plan. Stimulating applications, such as sulphur fumigations, or ointments with camphor, &c. are not to be used in the acute forms; but when much of the activity of the eruption is subsided, and the harsh chronic state of the skin, mentioned before, supervenes, then baths of the sulphuret of potash or of the sulphureous mineral waters will be very proper. In this state the ointment of the proto-ioduret of mercury, mentioned in the article Lepra, has been used with decided benefit.

In lichen agrius it is advisable to commence the treatment almost always by a venesection. Nothing tends so much to allay the vehemence of the burning pruritus. This practice will be more pointedly indicated if the patient be young and vigorous, but we consider that it is not less useful in an opposite condition. The application of leeches in the neighbourhood of the inflamed papulæ will also prove a very effectual sedative for the painful itching, but in their use it must be carefully observed to place them exterior to the inflammatory area. Every thing said with respect to the necessity of an antiphlogistic diet is still more indispensable to observe here while any fever remains, or while the inflammation displays any activity. Under these conditions, every local stimulant must be avoided as worse than useless. Emollient poultices, with some Goulard's extract sprinkled in them, will sometimes be found to assuage the irritation, but if used more than barely lukewarm, they will only increase it. The almond-milk embrocation will answer this end probably as well as any other. Dr. Elliotson recommends, as the best means for allaying the tingling and itching,

a lotion of chloride of lime or soda, to be used very dilute.

If under depletory means the eruption loses much of its intensity, then the exhibition of tonics will often prove highly serviceable. The decoction of cinchona with sulphuric acid is preferable to any other. This is especially useful in the cases of broken-down, dissipated subjects, and where the constitution has been brought rather low by antiphlogistic measures. It is not to be imagined that there is any thing contradictory in this practice of first reducing the system by depletory means, and then administering tonics as it were to restore it; on the contrary, the practice is found not only compatible with theory, but experimentally good. In fact, where we have to do with impaired constitutions, the abstraction of blood will be useful, as the tonics will act with greater certainty and efficacy after it, than if they be trusted to without it. With respect to the diet in this stage of the affection, it should be still kept of a very light kind; but it is to be borne in mind, that where the disease has supervened in an individual whose digestive organs and system generally have been greatly impaired by habitual drinking, it is expedient to allow him a small portion of his accustomed stimulus. This is another fact confirmed by experience and reconcileable to pathological principles.

Where it has fallen into an inveterately chronic state, lichen is a very intractable malady. Sulphur fumigations, sulphur and alkaline lotions, have in this case been found beneficial. Mercurial preparations have also been recommended. If obliged to have recourse to this mineral, we would prefer trying the proto-ioduret of mercury to any other preparation, from what is known of its effects in some other cases; one grain twice a-day is a sufficient dose for an adult. With its internal use, might be properly joined the local application of the ointment of the same preparation. We believe, however, that Fowler's arsenical solution is the best internal remedy in those inveterate cases; it is to be given in doses of from three to eight drops thrice a-day, and continued for at least a month. The cautions usual in its exhibition are of course to be strictly observed.

J. Houghton.

LIVER, DISEASES OF.—The liver, in common with other organs, is liable to certain morbid changes of structure, usually designated "organic disease." The application, however, of the epithet "organic," has been neither very precise nor correct; for it is used to express every description of alteration, from simple congestive tumefaction to complete disorganization or alteration of structure or tissue. In the present [general] article, we propose to consider the diseases of the liver (hepatitis excepted) [which will follow in a distinct article] and its membranes, and the general effects of them upon the economy at large. Many of these are purely the effects of inflammatory action of some kind; many the result of morbid growths or accretions, and present morbid changes of structure, induced by causes the nature and operation of which are not satisfactorily ascertained. These affections may be arranged under two general heads or divisions, namely, those affecting the investing membrane, and those affecting the more immediate substance of the liver.

I. Diseases affecting the Investing Membrane of the Liver.

The diseases affecting the investing membrane of the liver are mostly the result of inflammatory action. Inflammation, when confined to the membrane, is generally also confined to the anterior or convex covering. Sometimes, however, it occupies those portions in contact with the stomach and duodenum. The effect is a layer of coagulable lymph. This layer gradually concretes, becomes more or less organized, and firmly attaches the peritoneal covering of the liver to the contiguous parts, producing what are termed "adhesions." In some cases, the adhesions are so generally diffused over the whole surface, and the contiguous membranes so closely united, as to seem one simple but thickened membrane, nor can the separation be effected without sufficient violence to lacerate the original membranes, and separate them from their natural connections. More frequently, however, these adhesions are formed by membranes of considerable length, in many instances resembling the processes known more commonly as "the ligaments of the liver." The substance of these adventitious membranes varies in different cases; in some, it is extremely delicate, pellucid, transparent, and beautifully interwoven. In others, it is much denser and firmer, and frequently crossed or intersected with strong, inelastic, ligamentous-like bands. The author has now in his possession a membranous connection of this sort, about five inches in depth, and which is traversed on each side by strong unyielding bands of this description, several lines in thickness.

In many cases the membranes present no appearance of unusual vascularity; but it not unfrequently happens that the whole surface is covered with minute vessels, intersecting each other in every possible direction. These vessels are sometimes of a bright vermilion, sometimes of a purple colour. In such cases, these adventitious membranes are in a state of inflammation, and give rise to all the local symptoms of severe inflammation of the contiguous viscus, without the constitutional excitement so invariably accompanying a true phlegmasia. It may be as well to explain the nature of symptoms which frequently prove embarrassing to the practitioner.

These connecting membranes, being of foreign origin and the production of disease, are not so intimately connected with the system as those which are more immediately and essentially parts of the natural organization, and exert no direct influence upon the animal economy. Consequently, when diseased or inflamed, they become mechanical sources of impediment, rather than causes of constitutional derangement. Like all other organized parts, they exhibit sensibility and all the other manifestations of vitality, but still the sensibility is probably much inferior to that of the essential organizations; or, at all events, from their loose connections, and the total absence of all functional contribution, they do not appear capable of influencing the economy, like the other parts, more intimately connected, when labouring under disease. It is obvious that the treatment

will consist in mere local measures, such as leeching, cupping with scarification, blistering, &c. Dry cupping is often very efficacious in such cases.

Sometimes the coats of the liver are converted into cartilage. Dr. Baillie, however, states that this happens much more frequently in the spleen than in the liver. The cartilaginous conversion is generally smooth, thin, and soft in its texture. Sometimes small fat-like excrescences are observed upon the surface of the peritoneal covering. They vary in size, from that of a pin's head to that of a pea. They often partake of the character of tuberculous accretions, and their consistence varies from a mere pulp to a hard fatty mass. They are not important in a practical point of view.

II. Diseases of the Liver.

The diseases of the liver may be divided into those affecting its immediate structure and those affecting its appendages.

Morbid Anatomy of Diseases of Structure.—A very common effect of previous disorder is preternatural evolution of volume from simple tumefaction. It is the consequence of an unnatural accumulation of blood in the vessels of the liver. It is that condition described by the French writers under the term **hyperæmia,** and may be either general, that is, pervading or occupying uniformly the entire of the organ, or more partial in its extent. When general, the liver presents a degree of redness uniformly diffused throughout. Its volume is considerably enlarged, but of the natural consistence; and its absolute weight, as well as specific gravity, is increased.

If an incision be made into a liver in this condition, black fluid flows out very abundantly. It often happens, however, that the hyperæmia is more partial, appearing in distinct patches, and forming red spots, varying both in figure and extent, in different parts of the liver. These spots are rendered more conspicuous from the contrast presented by the surrounding paler parenchyma. The colour arising from hyperæmia will vary according to circumstances. In some instances it assumes a dull brick red; but in most cases it is of a reddish purple, which is readily reconcilable with the sources of supply.

Andral asserts that hyperæmia is of three kinds. The first he considers as arising from irritation, which may be either idiopathic or sympathetic of—"subsequent to"—a similar affection of the alimentary tube. The second description he considers to be wholly of a passive nature, the blood accumulating in the parenchyma, exactly as it accumulates in the gums in scurvy. The third kind he looks upon as purely mechanical, arising from obstruction of some description or other in the right side of the heart; "the blood then stagnates in the supra-hepatic veins, and obstructs the liver." (Vol. ii. p. 588.)

The same authority asserts that "congestion of the liver from a mechanical cause" often takes place in infants during parturition. Such infants have the liver so gorged with blood, that the vessels give way, and the blood is extravasated under the investing membranes on the anterior or convex surface. M. Billard states that effusions of blood into the cavity of the abdomen, in consequence of such a turgid condition of the liver, are by no means uncommon.

Hyperæmia may be considered as comprehending several distinct varieties, differing as to their seat and nature. It may take place, for example, in the larger vessels, producing that species of plethora more properly designated *engorgement.* In this species the larger arteries and veins are preternaturally distended; and the flow of blood on section of the substance will be immense. It may also be complicated with a sub-inflammatory condition of the vessels, particularly of the veins.

When we consider the peculiar character of the circulation through the liver, and the nature of the vascular structure by which the function of the organ is performed, we can have no great difficulty in understanding the subacute character of the symptoms even of what may be termed the more active diseases of the organ. The function of the liver, contrary to that of most other organs, is performed through a venous rather than an arterial tissue; and hence almost all the diseases of the liver manifest the congestive or the veno-congestive character; that is, symptoms are either almost altogether absent, or they are of the more obtuse description. Very often in the congestive affections there is no obvious manifestation of disease, till the liver has acquired a volume incompatible with the space naturally assigned for its accommodation; and the attention of the patient is attracted, not by the primary affection, but by the secondary ones. But when the disease partakes of the nature of veno-congestive inflammation, then we find those subacute symptoms characteristic of this species of inflammatory action; such as dull pain, a slightly excited circulation, and the other symptoms of constitutional participation.

The inflammatory affections of the liver are always more slow in their course, and their terminations, unless by resolution, are more protracted. Hence suppuration, abscess, &c., are much longer deferred than in organs the structure of which renders them liable to real inflammation. Upon these principles we can understand, or at least plausibly account for, the utility of mercury in the early periods even of what are named inflammatory affections of the liver. They are all mostly of the congestive or veno-congestive character, and mercury seems to exert a specific exciting influence upon those parts of the vascular system which are more especially the seat of such congestions.

The structure of the liver is found to consist of two substances: one apparently formed by the ramifications of its capillary vessels, presenting a reddish appearance; the other a yellowish white, and which is supposed to be chiefly concerned in the secretion of the bile. Although these two substances are in the natural state distinct, yet some care is necessary to prevent their being confounded. In engorgement, however, they are not to be distinguished, and, consequently, a uniform redness—purply redness—pervades the entire viscus.

The blood sometimes escapes from the vessels, and is effused into the parenchyma, producing a species of bloody infiltration, named by the French writers *hepatic apoplexy.* Sometimes it arises from the rupture of a single, but large vessel, dis-

tributed in the liver. In other instances, there is no perceptible rupture of any of the vessels; but spots are perceived dispersed in various parts throughout the organ. These spots, on being examined, are found to consist of blood, either in the fluid state or coagulated. Andral relates an instance in which, besides various collections of fluid and semi-coagulated blood, there were found some spots of a firmer consistence, in the centre of which were several fragments of hardened fibrine, deprived of the colouring matter. The examination of this condition induced him to investigate the question, whether fibrine thus deprived of its colouring matter might not be the origin of certain accidental productions, encephaloid and others, frequently found in the liver; a conjecture in which he was confirmed by the examination of another liver, in which he was able to trace the different changes of the blood, from its perfectly fluid state till it passed into a substance resembling precisely the encephaloid in all its characters. (Vol. ii. p. 589.) Cruveilhier states that the first degree of hepatic phlebitis is often a circumscribed infiltration of blood into the tissue of the liver. (Dictionnaire de Médecine et de Chirurgie, t. viii. p. 326.)

Anæmia is a condition directly the reverse of the foregoing, in which the viscus does not receive its due proportion of blood. This, however, more frequently arises from some morbid condition of the organ diminishing or obliterating the calibre of its vessels, as induration and various other organic changes. If, for instance, the white substance of the liver be preternaturally developed, the red remaining either in its natural condition, or becoming altered in its colour, while its bulk diminishes as the red part wastes, it becomes less vascular; condensation takes place; it is converted into a species of cellulo-fibrous tissue, and the vessels are obliterated.

2. *Derangements of the nutritive functions.*— The process of nutrition and growth is subject to morbid derangements in the liver as well as in other organs; and in fact there are, perhaps, but few parts of the animal body in which such derangements are so frequent. They are not only very various in their nature, but give rise to various and frequently very opposite results.

Hypertrophy of the Liver is a condition in which its volume is increased. This condition may be confounded with simple hyperæmia, in which the bulk is also increased; but they are affections of a very different character, the one being a preternatural accumulation of blood in the vessels; in the other the increase of volume depending upon the preternatural development of substance.

The hypertrophy may be general, that is, the entire structure hypertrophied; or it may be partial, confined to particular portions of the structure. The organ, also, may present various appearances as regards colour, consistence, and form. It may be pale, or red, or of various other tints, as green, grey, or brown; this last in parts degenerating into complete black. The consistence may be either increased or diminished; it may be firmer and harder,—having a denser and more solid feel,—or it may be softer, and more approaching to flabby. If the hypertrophy be equally and uniformly diffused, the change of form will be simply enlargement. But in some instances the hypertrophy is partial, and one constituent may be hypertrophied, while the other remains in the natural state, or even runs into atrophy. This may give the liver "a lobulated, mamillated, or granular appearance." (*Andral.*)

Hypertrophy may also be considered in reference to extent. Thus it may occupy the whole of the liver, or only one or more of its lobes. When one lobe only is hypertrophied, it appears to constitute the entire of the organ, the remaining parts appearing more like appendages. When the right lobe is extensively hypertrophied, the left seems quite diminished, or to have nearly vanished. In the case of hypertrophy of the left lobe, the right seems to have diminished in size. The hypertrophy of the right lobe is sometimes such as to cause it to project considerably below the ribs, and in children sometimes to extend nearly to the ileum, occupying the whole lumbar region, and a great portion of the epigastrium. When the hypertrophy exists in the left lobe, it will often extend into the left hypochondrium, and not only may be, but has been, mistaken for an enlarged spleen. More frequently, however, it occupies the epigastrium, and the practitioner should be aware of this fact, because such projections, by careless or hasty observers, may be mistaken for gastric tumours, or for diseases of the transverse colon.

The lobulus Spigelii, it has been asserted, is found frequently enlarged. More modern observation, however, has not confirmed the assertion. It certainly is sometimes enlarged, but it does not appear that it is often found in a state of isolated enlargement.

According to Cruveilhier, a considerable development may arise from accidental productions found in the substance of the organ. But this is not hypertrophy properly so called. It is not uncommon, however, to observe such tumours accompanied with a true hypertrophy of the tissue of the liver itself; so that there is at the same time with adventitious tissues an augmentation of the proper substance of the organ. In other cases the liver is the seat of an extravasation, from which results a pure and simple augmentation of volume without any alteration in its substance. (Dict. &c. p. 326.)

In the fœtus, and for some time after birth, the liver maintains a volume very disproportionate to that which it subsequently preserves. As age advances, the size of the liver comparatively diminishes, and it appears much reduced; it is consequently retracted, or rather drawn upwards, and its edge can be no longer felt projecting below the margin of the ribs. This is the natural condition; but in some cases this natural reduction in volume is so far from occurring, that the growth increases, and the liver becomes still more disproportionately enlarged. Thus the hypertrophy may continue progressively after birth, or it may cease for a while; and the liver, after having retired nearly within its boundaries, will suddenly, and without any manifest cause, continue to increase, until it arrives at an incredible and most distressing size. This state of the liver is very often merely one of that combination of perver-

sions in the nutritive functions which together constitute the scrofulous diathesis.

Atrophy is the directly opposite condition of that just considered. Atrophy, though generally accompanied with reduction in volume, yet is not necessarily so. It may extend to all the lobes, or affect only one. Like the preceding condition, it may also be attended with induration or softening.

Though generally attended with a diminution of size, yet an augmentation of volume is by no means incompatible with an atrophied condition. Sometimes the size of the organ, though atrophied, exceeds the natural, and the atrophy consists in the removal of the proper tissue, cellular tissue being substituted in its stead. In these cases there is a defect in the organization, and the structure, as it were, reduced to its primitive frame-work, presents extensive patches of cellular tissue. This tissue is sometimes formed into serous, or contains hydatids, or it may become hypertrophied; which, it is argued, so far from implying an increase of organic action, rather indicates a deficiency; the tissue being unequal to the production of the true parenchyma, degenerates into a serous cyst. The atrophy may be partial, and then the glandular grains which have not been atrophied become enormously developed, to supply, as it were, the deficiency caused by those which have been removed.

Cruveilhier states that he has sought in vain in the vessels of the liver, whether arterial or venous, for the cause of the atrophy of the organ. They are diminished in a ratio directly proportioned to that of the liver, but nothing tends to show that this diminution has been a primary operation. (Loc. cit.)

Atrophy of the liver is observed in a great variety of circumstances. In some cases of retention of bile in consequence of the extreme distension of the hepatic ducts, the liver has been reduced to half its natural size. In indurations, too, it has appeared atrophied, so that its glandular structure was hardly to be recognised.

The partial atrophy seems in general to arise from pressure upon the liver, either by tumours found in the immediate neighbourhood of the organ, or from those formed in the substance of the viscus itself.

Induration.—This state may exist simply, or combined with hypertrophy or atrophy. The colour varies, being either a purple or lighter red, or grey olive or brown. On cutting into a liver in this condition we observe no peculiarity of structure, but it appears rather a confused and undefined mass. The surface of such livers not unfrequently presents the appearance of membranous threads, of a radiated figure, the lower edge bent a little forwards. Baillie considered this the first step in the formation of the common tubercular liver. He observes, "I have sometimes seen very small tubercles formed upon a part of the surface of such a liver, which were exactly of the common sort. From this appearance it is probable that additional matter is deposited in the interstices, through the general mass of the liver, rendering it much harder, and that this matter, together perhaps with part of the ordinary structure of the liver, is converted into tubercles." (Morbid Anatomy, c. ix. Diseased Appearances of the Liver.)

Cruveilhier has often found indurated livers of a green olive colour, of great density, tearing or giving way with extreme difficulty, and of a volume less than in the natural state. The glands appear atrophied, and the fibrous envelope of each granulation thickened. In place of bile, the biliary vessels contained a kind of serosity tinged of a bright yellow. In a patient who died, after a tedious green jaundice, in a manner similar to those who died of cancer in the liver, the only alteration discoverable on dissection was that above described. By far the greater proportion of indurations of the liver are accompanied with a diminution of its volume.

Softening.—This condition is said to be as common as the foregoing, which, however, does not accord with the writer's experience, at least among the troops; still it must be allowed that softening is a very frequent morbid condition. There seem to be two degrees of it: in the one the softened consistence is not perceptible unless it be compressed between the fingers; it then readily gives way, becoming a kind of pultaceous mass.

In some cases the liver is so softened that it is impossible to detach it without tearing it into shreds; and when the peritoneal covering and proper investing membrane are broken, they reduce to a sort of brownish yellow pulp. This alteration has been looked upon as cadaveric, a view, however, which appears to be unfounded. The liver itself appears a kind of pulp deprived of every semblance of organization. It has no fetid odour. When put into water, an immense number of small yellowish granules appear. These are quite distinct, seem as if dissected, and resemble the small seeds which present in dried grapes or raisins, attached to the large vessels by vascular pedicles. In the other the softening appears evident to the eye, and somewhat resembling that acquired during long-continued maceration. The vessels, or at least the extreme branches, seem to float in a reddish or greyish-looking pulpy mass, and which seems to be nothing more than the dissolved parenchyma.

The colour is in some instances natural; if, however, there be hyperæmia, the colour will be purple or brown, but it frequently happens that in consequence of some modification of structure, the colouring matter of the blood cannot penetrate the tissue, and it appears remarkably pale. In such cases the only traces of blood are confined to the large vessels.

Baillie, under the head of softened substance of the liver, states that it is found much more flaccid than natural, without any other appearance of disease. It feels as soft as the spleen to the touch, and is then mostly of a leaden (q. v. purple) colour. This change he considers must arise from a process similar to what Hunter named "interstitial absorption," the absorbents removing insensibly the very minute parts of structure without ulceration. This state he looks upon as mostly confined to advanced age, being rarely, if ever, found in very young persons.

Tubercle of the Liver.—Baillie notices several forms of tubercle in the liver; such as

common tubercle of the liver, large white tubercle of the liver, soft brown tubercle, and scrofulous tubercles.

Common tubercle is confined to persons of middle or advanced age, being very seldom met with in young persons. It is likewise more common in men than in women, and more apt to occur in persons addicted to spirituous liquors. Baillie describes such tubercles as near each other, of a rounded form, and giving an appearance of irregularity to the surface. They consist of a brownish or yellowish white solid matter. They vary in size from that of a pin's head to that of a hazel-nut, some of them even exceeding this. The liver is in such cases indurated, and its lower edge bent a little forward. The liver itself is of the healthy size, or sometimes smaller, and on section of the substance the patulous vessels seem reduced in their calibre. The colour of the liver is yellow, which is attributed by Baillie to the accumulation of bile in its substance; and as this condition is almost uniformly accompanied with ascites, the fluid accumulated in the peritoneum is almost always tinged yellow, from mixture with bile. The gall-bladder is described as being much contracted and white, from being empty. The bile, it is asserted by the same authority, from the pressure of the hard liver upon the pori biliarii, does not reach the ductus hepaticus, and consequently cannot pass into the gall-bladder. Permanent jaundice is also established, because it depends upon an unchangeable morbid condition of liver. When the jaundice has continued for a considerable time, the blood in all the blood-vessels of the body is found either not coagulated at all, or very imperfectly so; and this is attributed to the chemical influence of a mixture of bile with the blood. This is the appearance of what is named "scirrhous liver;" but it bears only a remote similarity to scirrhus as it appears in other parts of the body. (Morbid Anatomy, c. ix.)

Large white tubercle of the liver.—Under this name Dr. Baillie describes hard white masses sometimes formed in the liver, varying in size, being in some cases considerably larger than a chesnut, and in others a good deal less. They are more numerous near the surface than in the middle of the substance. They are in clusters, with the healthy structure interposed; are of a firm consistence, and constituted of an opaque whitish substance; they are hollow, or depressed upon their outer surface; and the liver is generally enlarged.

This form seems to be generated round the blood-vessels, as appears from making sections. It may or may not be attended with ascites. Sometimes bile is accumulated, tinging the substance of the liver, the colour remaining natural between the tubercular masses. Dr. Baillie asserts that he has observed a sort of pus lodged in these tubercles very much resembling that from scrofulous sores; and he therefore concludes that this species may be of a scrofulous nature.

Soft brown tubercle.—These generally consist of a soft, smooth, brownish matter; are about the size of a walnut, and mostly occupy the surface of the liver. They are a rare form.

Scrofulous tubercles. Tubercles resembling those found in the lungs of scrofulous or phthisical patients, are said to be occasionally found in the liver. They are said to resemble them precisely, except in being a little browner in colour. They are dispersed and solitary, and do not give that irregularity of appearance attendant on the other forms.

The liver in children is frequently found in a tuberculated state. The tubercles are about the size of a millet-seed, hard and semi-transparent, so as to be sensible to touch as well as sight from their density, but yet would escape a careless observer.

Such are the forms and varieties of tubercle enumerated by Baillie; but there is reason to believe that the nature of these appearances was not thoroughly understood in the days of that highly distinguished anatomist.

It has been already observed that the structure of the liver consists of two distinct substances; the one a reddish purple, formed by the capillary ramifications; the other of a whitish or yellowish colour, and which seems to be the part which secretes the bile. In the natural state these two substances are distinct, but an excess of blood destroys all distinction. On the other hand, a deficiency of blood renders the yellow substance more distinct and evident; and the privation may be such that the reddish substance may be deprived altogether of colour, and the liver assume a whitish tinge throughout its entire substance.

This appearance may be very much modified as changes predominate in the texture of the parts forming the hepatic mass. The yellowish substance may become hypertrophied, and this admits of various degrees. In one kind the substance is marked by the transit of whitish lines; in the other it is granulated; and these granulations, whether isolated or agglomerated, assume the appearance of yellow wax. These granulations Laennec considered as an accidental (adventitious) tissue generated in the liver, and named it, from its colour and appearance, "*cirrhosis.*" He also asserts that what he terms cirrhosis is accompanied by a shrivelled state of the organ; and it is almost always accompanied by ascites. (See Baillie on the common tubercle of the liver.)

Cruveilhier, who has given an excellent plate of this condition, (Anatomie Pathologique du Corps Humain, 12e livraison, planche 1re,) has examined and described its minute anatomy very attentively and accurately. He found the liver reduced to about a third of its ordinary weight and volume: the right and left lobes nearly equal in size, but remarkably altered. This double character, diminution in volume and change, is a very constant occurrence in these affections. The tissue is also denser than is natural.

The surface of the liver is not smooth but roughened by a number of granulations (tubercles), between which there are depressions, wrinkles, and thickenings, and the organ might be said to be dried up, as it were, withered, its investing membranes irregularly thickened, and opaque in many parts. Cartilaginous laminæ were found upon the inferior surface of the left lobe, and which were part of the peritoneum.

The colour is yellow, varying from a bright or canary to a brown yellow, depending upon the

fluid with which the tubercles are penetrated. These tubercles, if squeezed upon white paper, tinge it yellow. The quantity of colouring matter, though various in the different tubercles, seemed in direct proportion to their size. The blood-vessels traversing the tissue were found healthy, but the blood which they contained was serous (watery); the biliary-ducts and the gall-bladder full of a yellow bile, more or less inspissated.

On removing the investing membrane, which was done in several places, the tubercles were found to differ in size; and some, of the size of large peas, had a number of others beside them of the size of millet-seeds; and this gave the irregularity of surface to the liver. Each tubercle was found to be perfectly distinct and unconnected with the neighbouring ones, was provided with its own proper membrane, and was connected with the liver only by a mere vascular pedicle.

On a section of the liver these observations were confirmed; that is, the separate existence of the tubercles and their colour. But farther, it demonstrated that there existed, independently of the tubercles, a very dense fibro-cellular tissue, altogether foreign to the natural state. A section of one of these tubercles, examined by the microscope, presented precisely the same characters as the section of a healthy liver, namely, a spongy tissue analogous to the pith of a rush.

On examining into the characters of these tubercles, they seem to be nothing more than an unnatural development of one structure at the expense of the other—"une dissociation des deux élémens naturels de cet organe: les masses jaunes, fauves, constituant le tissu accidentel appelé cyrrhose, ne sont autre que les granulations sécrétoires, se désorganisant graduellemen par l'effet de l'oblitération du lacis vasculaire, et l'obstacle à la circulation hépatique qui en resulte." (Mémoire par M. Bouillaud inseré parmi ccux de la Société Médicale d'Emulation, tom. ix. p. 170.) The examination also proved that nothing more is neccssary to give a tuberculated appearance to the liver than an unusual development of the acini, and hence it is unnecessary to suppose the production of a new tissue to account for the phenomenon.

[M. Cruveilhier, however, does not admit that the granules are formed of two distinct substances. His views of cirrhosis are, that it consists essentially in atrophy of the greater number of granulations, and hypertrophy of the remainder to supply the deficiency thus engendered. The two distinct substances in the liver—the yellow, the secreting tissue, and the red formed by ramifications of blood-vessels—are, however, by no means generally admitted, and until their existence is established, any theory founded upon them cannot be implicitly received. The views of Mr. Kiernan in regard to the minute anatomy of the liver (*Philosophical Transactions*, for 1833, p. 711, or the writer's *Human Physiology*, 5th edit. ii. 268, Philad. 1844) have given rise to another explanation which is considered by Dr. Carpenter (*Principles of Human Physiology*, § 659. Amer. edit. Philad. 1843) to be satisfactory. The small masses are regarded as uncongested patches, composed of parts of several adjoining lobules, and having one or more interlobular spaces as a centre; and the biliary plexus of these, being filled with bile, gives them their yellow colour. In the other, there is a more or less complete atrophy of the portions of the substance of the liver intervening between them, so that the size of the liver is much diminished. This may be the true explanation; but, as elsewhere remarked, (*Practice of Medicine*, 2d edit. i. 600, Philad. 1844,) the opinion of Laënnec has appeared to the author to be most entitled to favour; and the circumstance, that, in certain forms of cirrhosis, little granules, having the appearance of adipocire, can be washed out of their cellular fibrous capsules, after a maceration of some days in water, is greatly in favour of their adventitious formation. The matter, of which the rounded masses in cirrhosis consists, is not considered by Mr. Goodsir (*Lond. and Edinb. Monthly Jour. of Med. Science*, May, 1842) as a new deposit, but merely as the natural tissue of the liver, altered by the pressure exerted by its fibrous envelope. These alterations consist in constriction, more or less powerful, of the vessels and ducts which pass out of and into the rounded mass; the necessary difficulty with which the circulation is carried on, and the bile advanced along the ducts; and, latterly, in a change in the constitution of the nucleated cells themselves, which, instead of being distended with bile containing oil-like globules, contains matter of a darker colour than oil. The cells may at last contain matter perfectly black, and then the rounded mass assumes the appearance of a melanotic tubercle,—the black cells, in some instances, being pyriform and caudate. Mr. Goodsir does not state the exact nature of these various changes in the liver, although he is inclined to believe that the forms of cirrhosis and melanosis are due to the contractile tissue, as a product of inflammatory action more or less acute. His remarks on the whole subject can only be regarded, however, in the light of suggestions.]

Tubercles in the livers of adults are very rare, and Cruveilhier asserts that he never met with them in the numerous cases of pulmonary and abdominal phthisis which he has had occasion to examine.* He states that he has seen the liver of an individual full of tubercles, each formed by a dense cyst containing a drop of pus; at the same time there were a great number of calculi in the biliary passages. The small multilocular or unilocular cysts formed by the roots of the excretory biliary ducts are often confounded with and mistaken for tubercles, when containing small calculi, or a liquid tinged with the bile. Cruveilhier has very often met with this kind of alteration in both the livers of newly-born children and in adults.†

Erectile Tumours of the Liver.—Cruveilhier describes an affection of the liver in which the tumours resemble the tissue of the corpus cavernosum penis. They are very common not only in the liver but in other organs. Sometimes they are solitary, sometimes numerous. They appear to be formed of a greater or less mass of granulations, and are capable of an indefinite increase.

* "Les tubercules du foie sont très rare chez l'adulte; je ne les ai jamais rencontré dans les cas nombreux de phthisie pulmonaire, de phthisie abdominale, que j'ai eu occasion d'examiner." Dictionnaire de Médecine et de Chirurgie, tom. viii. p. 329.

† Ibid. p. 330.

In one instance, in the centre of the tumour there was a mass of fibrous tissue, from which prolongations extended, which in their growth passed in all directions. In another instance a carcinomatous tumour accompanied the erectile. (Dictionnaire de Médecine, &c. p. 330.)

Flaccid Liver with Reddish Tumours is a state noticed by Baillie, in which the liver is unusually flaccid, and studded with large reddish soft tumours, containing a thick pus. They were found in a person presenting the leading characters of the scrofulous diathesis. He considers them in some measure analogous to fungus hæmatodes.

Fatty Liver.—This is a condition more common in the lower animals than in man. While a fatty or adipose state of the other organs and the muscles in particular seems to be the last stage of atrophy in them, the same appears to be the last stage of hypertrophy in the liver. The fatty liver in the human subject never assumes that complete adipose transformation induced in the livers of geese, ducks, &c. by the agency of the most absolute rest or inactivity, darkness, and the artificial ingestion of an immense quantity of alimentary matter. The liver, however, in the human subject undergoes, to a limited extent, a true fatty transformation. The discoloured liver observed in cases of phthisis is frequently confounded with the true fatty transformation; but chemical analysis disproves this opinion, by showing that the fatty material does not exceed the proportion naturally belonging to the normal condition of the organ.

[Recently, Mr. Bowman has suggested, and Mr. Goodsir accords with him, that the fat in adiposis of the liver is deposited within the nucleated cells of the organ, and that the disease is to be considered, in part, as a redundancy of the oil-globules naturally existing in these cells, with atrophy of the other structures.]

Phlebitis of the Liver. — This affection is frequently a consequence of inflammation of some of the other veins. It frequently follows large wounds or surgical operations, and is thus not unfrequently an antecedent to traumatic abscess. Cruveilheir asserts that he has often induced it by the injection of irritating agents, into either the general venous system or into the vena portæ. (Dictionnaire de Médecine, p. 327.) The circumscribed inflammations of the liver consequent upon phlebitis present every degree from the red induration to the actual formation and collection of pus. It has also been caused by inflammation of the hæmorrhoidal veins. Thus Cruveilhier relates an instance in which long-continued, violent, but ineffectual efforts to reduce an old prolapsus ani produced so much irritation of the rectum, that inflammation of the hæmorrhoidal veins succeeded, which extended to the veins of the liver, and terminated in a number of abscesses, both superficial and deep-seated, in this organ. The phlebitis may be confined wholly to the capillary system, as it may at the same time occupy both the large veins and the capillaries.

Cysts are often observed in the liver, of which the causes are various.

Hydatids are very often seen in the liver, and are mostly contained in a cyst. The cyst is formed of dense, firm, unyielding material, something like leather or fibro-cartilage. It is generally laminated. The laminæ are composed of white matter; and the cavity is sometimes divided by a partition formed of the pulpy substance lining the laminæ. (*Baillie.*) The cyst may contain a single hydatid, or they may be numerous.

The hydatids are found loose in the cavity, and floating in a clear transparent fluid. They appear like small, rounded, sometimes oval-looking bags, which are said to consist of a white semi-opaque pulpy matter, containing a fluid capable of coagulation. (Ibid.) In an examination of a liver containing a cyst full of hydatids, which occupied more than three-fourths of its volume, leaving but a small portion of the right and left lobe free, the writer found the hydatids perfectly transparent and pellucid. In this case the liver was reduced in size, and the emaciation and contraction of the intestines were such that the bodies of the vertebræ could be distinctly felt through the abdomen, and counted. It might be almost truly said the peritoneum lining the interior muscles of the abdomen rested upon the bodies of the vertebræ.

In some cases the colour is of a lightish amber. The bag in which the hydatid is contained seems to consist of two laminæ, and to possess a contractile power. The larger hydatids are occasionally found to have smaller ones attached to them. In some cases the hydatids are connected, and even found to enclose each other like a set of pill-boxes; in other instances they are distinct and unconnected.

Hydatids are generally found occupying the substance of the liver, but occasionally they are attached merely to the outer surface, hanging pendulous into the cavity of the abdomen.

Cruveilhier (Planche v. troisième livraison,) describes a curious instance of ascites, anasarca, and icterus with "deux kystes acéphalocystes du foie." The patient, a man of thirty-eight years of age, and vigorous constitution, had been wounded, in 1814, in the epigastrium by a musket-shot. About the year 1828 he was troubled with vomitings, and with pains in the stomach, every fifteen days, and which had commenced about a year after his accident. He was bled, and leeches were applied, with other treatment. Scarifications were made on the extremities, subcutaneous inflammation followed, and he died comatose.

On opening the abdomen, instead of peritonitis, as was anticipated, nothing but a citron-colour fluid appeared. The liver presented a singular appearance. The antero-posterior diameter equalled the transverse and the vertical very nearly the same at the right as at the left extremity. The left lobe was atrophied, and the surface of the liver shrivelled, and roughened by granulations of unequal volume and differing in form. There were two large fluctuating tumours, one on the right and the other on the left. Superiorly they did not extend beyond the level of the organ; but inferiorly the left formed a kind of spheroidal bulging of considerable size. Both tumours presented superiorly a very bulging sort of appendix traversed by sanguineous vessels with very thin walls, and which would have soon burst into the peritoneal cavity. The cysts on being opened were found filled with a muddy yel

lowish fluid, in the midst of which were both entire and empty acephalocysts connected together and coloured yellow. On examining one in its perfect state there appeared some white points, like small grains of sand, more resisting than the other points, vulgarly but erroneously regarded as the germs or eggs of acephalocysts. The figures or shapes were very singular and varied, and which it is asserted the partisans of the vitality of these organized globules will refer to defects in the conformation arising from a straitened development. On examining the primary membrane lining the left cyst there were agglomerated tubercles roughening the internal surface, which might be compared to small eggs. In a portion from the right there were vesicles in clusters, some regular, some irregular, and which Cruveilhier thinks we should feel some difficulty in regarding as the germs of acephalocysts ready to detach themselves.

The enveloping cyst was fibrous and a quarter of a line in thickness. The internal surface rugous, as it were torn, and studded with concretions, in some places brown, in some green, in others yellow, and in some a most beautiful orange yellow; all which shades arise from the colouring matter of the bile some way modified. These concretions, which Cruveilhier asserts he has seen several times forming a thick lining or bed similar to biliary calculi, lining the entire of the cysts, prove evidently, he says, the communication, a temporary one at least, of the cyst with the biliary tubes or canals.

The cyst was easily detached; and a loose cellular filamentous tissue connected it with the liver, to the substance of which it was attached merely by a number of arterial and venous vessels and hepatic tubes, of which a great proportion was obliterated.

The cyst of the left lobe, which extended below the level of the liver, compressed the left division of the vena portæ, which was narrowed in an extraordinary degree, to which circumstance the atrophy of the left lobe in this case is attributed. The corresponding branch was on the contrary dilated.

On examining a portion of the liver by making incisions, it was found tuberculated, the tubercles separated by interspaces of different extent. In the interspaces the liver had a fibrous aspect, and did not present, in a given proportion, above half the glandular structure belonging to the natural state.

The subcutaneous phlegmonous inflammation with infiltrated pus, occupying the lower extremities and extending to the thighs, is considered by Cruveilhier to have been occasioned by the scarification of the anasarcous extremities, and to have been the cause of the succeeding coma, and ultimately of death.

Cysts containing an Earthy Matter have been found in the liver. They are generally formed of a kind of fibro-cartilaginous, dense, firm membrane. Sometimes it is partially ossified. The earthy matter is gritty, sometimes plastic, and of a whitish colour. It consists chiefly of phosphate of lime, and very probably is merely the commencement of osseous deposits in the substance of the liver.

Cysts containing Worms have been said to be found in the liver and likewise in the biliary ducts. Lieutaud relates instances of this sort, but they are very rare, and the fact seems even rather doubtful.

Rupture of the Liver is an injury to which it is exposed from external violence, and is an accident to which it is more liable than any other gland in the body. This greater liability Dr. Baillie attributes to two causes; first, its more exposed or rather less protected situation in thin persons, if the liver be enlarged; secondly, because its structure is such that it yields to external violence more readily than any of the others. The accidents from which such ruptures occur are heavy weights falling upon the abdomen or passing over it. The writer saw an instance of this sort at Chelmsford some years ago. A carter fell from his wagon, which was heavily laden, and the wheels passed over him in the region of the liver. He lived a very little time, but did not complain of much pain, except from the bruise. On opening the abdomen the cavity of the peritoneum contained an immense quantity of blood, the liver and spleen were ruptured, as was also the vena cava, from whence the hæmorrhage took place.

Traumatic Abscess of the Liver. — Abscesses after wounds, &c. are apt to form in different organs, but in none more frequently, after the lungs, than in the liver. These abscesses vary both in number and extent. Sometimes there exists but one, sometimes there are two or three small clusters. In some cases there is but a single abscess; and in an instance mentioned by Cruveilhier, of death in consequence of gangrenous inflammation of the pelvic cellular tissue, induced by infiltration of urine, on examination there was found but a single abscess in the liver, and seated in the loose cellular tissue which surrounded one of the divisions of the vena portæ. In other cases the liver presents an immense number of small spots or foci of a tubercular appearance.

On tracing these abscesses through their progress from their first formation, they appear at first as brownish bloody spots, which seem to be situated in the glandules themselves. 2. Infiltration of white concrete pus, which gives an appearance of granite to the liver, with a slate brown colour all round, without any other evident trace of inflammation. Sometimes a great number of the glandules are affected; in other cases it is limited to a very few, which with the density of the pus, the number of foci or clusters, and the irregularity of the masses affected, has given rise to the idea of their tubercular nature. The surface of the liver next the cluster always appears of a slate-brown colour, which is probably cadaveric. 3. A collection of pus of abscess, the dimensions of which exactly equal those of the masses first affected.

The causes of such abscesses are wounds of different kinds, surgical operations, and phlebitis. They seem to arise from the transmission of pus with the blood through the veins; a fact which accounts for the much greater liability of the lungs and liver to these kinds of abscess. The diagnosis is extremely difficult; sometimes there is pain in the right hypochondrium and right shoulder. In

other cases the region of the liver may be pressed upon it in every way without the slightest indication of sensibility. Jaundice is very uncertain. If, however, several days after a wound or surgical operation a patient should be seized with shivering, and suddenly sink into the extreme of a typhoid state, with no manifestation of disease in any of the other organs, a suspicion of the existence of this result may be entertained.

Abscesses sometimes, it is said, form in the liver in consequence of injuries done to the brain. This form is said to arise from irritation. The subject, though considered at some length by Cruveilhier and some other writers, requires further researches.

Melanosis.—The liver is liable to become melanotic. During the progress of the disease the liver sometimes enlarges to such an extent as to occupy nearly the whole of the abdomen, and in a female might be mistaken for pregnancy. A case of this kind is related by M. Ruyer in the Encyclographie des Sciences Médicales. The patient, a woman about thirty-three years of age, had enjoyed very good health till the month of June, 1833, about which time she was ill-treated by her husband, and in a very violent manner. He kicked her upon the chest and abdomen in several places, and several contusions were the consequence, which were wholly neglected. After some days, dull pains were felt in the region of the stomach, extending to the lumbar spine. In the course of a few days the pains disappeared without any treatment, reappearing however at uncertain intervals, with various degrees of severity, according to the exercise to which she was forced to subject herself. The abdomen at this period was of its natural size. In January, 1834, she was confined of a healthy child, which she suckled for eleven months. After confinement the belly diminished very little in size, and felt equally hard. She perceived that the abdomen enlarged, and she felt all the symptoms of pregnancy: she became much emaciated, and at last died. The abdomen was extremely hard and enlarged, and on opening it about three pints of a serous-looking fluid escaped. The liver filled up completely the whole of the abdomen, pressed the diaphragm high up into the thorax, extended into the right iliac region, and terminated by a protuberance of a spherical form. The entire structure was altered from the normal condition presenting a confused mass. Extensive adhesions existed between the anterior part of the stomach, a considerable portion of the transverse colon, and this hepatic degeneration. It pressed the whole of the intestines and other viscera against the vertebral column. It weighed twenty-four pounds. It was softer, more friable, and more easy of incision than in the normal state. It was of a violet brown slate colour, and studded with a number of whitish tumours, varying in size from that of a millet-seed to that of a hen's egg. The abscesses contained a homogeneous liquid of a purulent consistence. The gall-bladder was much enlarged; its contents almost black. The other abdominal viscera were natural. The vertical diameter of the thorax was reduced one-half; the heart of its usual volume, but displaced, its apex directed upwards; the lungs reduced in volume; their tissue soft, little crepitous, and easily torn; and there were numerous adhesions between them and the pleura costalis.

Cancer of the Liver.—The term cancer, as applied to diseased appearances in the liver, comprehends certain morbid productions deposited in its parenchyma. They are of different kinds, produce masses of various sizes and extent. They are mostly white, the white being sometimes mixed with red. Cruveilhier observes—"Of all the diseases of the liver, the most frequent and the most severe is, perhaps, the cancerous degeneration in the form of disseminated masses." They vary in extent, are somewhat spheroidal, and deposited in different parts of the substance of the liver, or near its surface in the midst of the perfectly healthy tissue, the organ appearing, as it were, filled with them. There is mostly a perfect line of demarcation between the tissue of these tumours and that of the liver, and the transition is abrupt, not gradual.

These tumours seldom appear solitary, that is, a single and only one, and in the few instances which Cruveilhier met with, upon close examination there existed a number of small miliary tumours, which from their tenuity would readily escape hasty observation. They vary in number from eight or ten to several hundreds or more.

These cancerous tumours are commonly confined to the surface. In a liver containing twenty tumours of this description, sixteen were found near the surface or superficial. (*Cruveilhier.*) The superficial ones are generally prominent, so that they can be felt through the abdominal parietes; and they may often be recognised by touch after the operation for ascites, frequently necessary in the advanced periods of this disease. But when they become large or extensive, they lose their spherical shape and become hollowed out or cupped in the centre, in consequence, probably, of the thickening of the corresponding cellular tissue under the peritoneum. The peritoneum itself often becomes thickened, fibrous, and cartilaginous; and adhesions take place between the liver and contiguous parts.

The situation in which the larger cancerous masses generally appear is the part which corresponds to the suspensory ligament, and consequently the antero-posterior ridge. Hence, perhaps, the reason why adhesions occur so frequently between the liver and stomach, and why these cancers open in the latter. The lobulus Spigelii is frequently affected, even throughout its entire substance, so as to appear a prominent encephaloid tumour. (*Cruveilhier.*)

These tumours also vary in size, from that of millet-seed to a turkey's egg, or the two fists, or even the head of a full-grown fœtus. From all the facts, their size, appearance, consistence, &c., it may be inferred that they are formed at different periods. There seem to be two varieties of them, which do not exclude each other; the hard or scirrhous, and the soft or encephaloid. These are generally considered but degrees of the same disease; but, according to Cruveilhier, this is incorrect, and the expressions, "period of crudity, period of softening," are improper.

The hard kind appears with an areolar web, which grates under the scalpel, composed of ex-

tremely dense, fibrous, and sometimes even cartilaginous meshes. It may be said that the tissue is fibrous, or even cartilaginous. There are small cavities in the centres of the tumours, filled with a fluid, crossed by fibrous bands more or less regular. On the pressure a lactescent cancerous juice exudes. If macerated in water or a weak solution of chlorine, the cancerous matter is dissolved, leaving a marginal fibrous tissue behind, somewhat analogous to the erectile. Sometimes the centres of the tumours are overrun by blood-vessels well developed; in others the vessels are so reduced in calibre, that it requires some attention to discover them. The soft kind is of a greyish white colour, resembling the infant brain. It is the encéphaloïde cancer of Bayle and Laennec. In some cases it is very white when not much overrun with blood-vessels, but where the vessels are numerous the quantity of blood gives it the character of apoplectic spots.

Ossification.—Bony depositions are sometimes found in the liver. The writer once met with a piece of bone imbedded in the substance, about the size and somewhat of the shape of the human patella. It resembled common bone, consisting almost entirely of phosphoric acid and lime, with a very small proportion of the carbonate of this earth. The upper surface rose very little above the level of the liver, and its entire depth or thickness was imbedded in the parenchyma.

Diseases of the appendages may be divided into those of the ducts and those of the gall-bladder.

Dilatation of the biliary ducts.—The cystic, the hepatic, and the ductus communis choledochus are liable to dilatation; mostly effected by large gall-stones making their passage through the duct, which sometimes is so far dilated as to measure an inch in diameter. (*Baillie.*)

Obliteration is frequently produced by inflammation, especially of the inner surface, terminating in adhesion. Hyperæmia of the mucous lining may cause such a swelling as will totally obstruct the passage of the duct, and this obstruction, however induced, may give rise to jaundice. Long-continued irritation may induce hypertrophy of the sides of the ducts, and produce an obliteration, the duct itself being transformed into a fibrous cord. Thickening and hardening of the duodenum or pancreas may, by compressing the ducts, obliterate them.

The gall-bladder is likewise subject to certain alterations; such are adhesions, ulcerations, thickening, and ossification.

Gall-stones are frequently found in the biliary ducts and in the gall-bladder. Sometimes the gall-bladder is completely filled with them, and then it is usually much enlarged. The number varies, but it is occasionally very great:* sometimes but one is found; it is generally very large; when numerous, they acquire different shapes from friction. The writer was furnished with two passed by a lady, which were flattened somewhat like a bean; the area about half as large again as a shilling, and much thicker than a bean. They were brown, smooth, and polished outside; sawn through they presented a bluish slate-coloured appearance; fracture rather striated; they consisted of phosphate of lime, trace of carbonate, and some animal matter. There was very little cholesterine in proportion to the other components. They were extremely hard.† These biliary concretions occupy all parts of the liver, the biliary ducts as well as the gall-bladder, and the larger ducts for the transmission of the bile. They produce frequently great irritation, inflammation of the mucous tissue, ultimately terminating in ulceration. In some cases the dilatation of the gall-ducts will allow them to pass into the intestines, and they are then voided by stool. Cruveilhier has given two very excellent plates illustrating the different situations and effects of these concretions upon the tissues.

Bile.—The bile, as might à priori be inferred, is liable to morbid changes, and it possibly might be presumed that the extent of these changes would in some degree correspond with the alterations in structure of the secretory organ. This, however, is far from being the case; and observation has been unable to establish any uniform connection between the alterations in the liver and the qualities of the bile. In many cases of severe organic disease of the liver, the bile appears to undergo little change; and the most obvious changes in the bile, and the most considerable augmentation in quantity, are sometimes accompanied by no recognisable change in the normal condition of the secreting organ. It is true we very often estimate the quantity secreted by a very uncertain scale, namely, the quantity discharged from the intestinal canal or the stomach in bilious diarrhœa and in cholera. Neither the quantity nor quality of the fluids secreted from the blood depend absolutely and essentially upon the normal conditions of the organic structure of the organs; and the experiments of Magendie have shown that the composition of the bile, and even its quantity, may be altered and increased at pleasure by changing the food of the animal.

Cholesterine.—Chevreul detected in human biliary calculi a peculiar crystalline matter, which he named cholesterine. Fourcroy considered it analogous to adipocire, and so named it; but Chevreul has shown that it is an independent principle. It is a brittle, lamellated, brilliant crystalline solid, somewhat like spermaceti in appearance, from which it differs by being infusible under 278° Fah., and in not being converted into soap by a solution of potass. It is devoid of taste and smell, and is insoluble in water. It dissolves in boiling alcohol, but is deposited on cooling in white pearly scales. According to Chevreul, its analysis yields—

Carbon	85.095
Hydrogen	11.880
Oxygen	3.025
	100.000

Nitric acid converts it into an acid, which has been named cholesteric acid, insoluble in water, but perfectly soluble in alcohol, especially if heated. Taste styptic, odour that of butter; lighter than water, and fusible at 136½° Fah. In quantity it is of an orange yellow tint, but eva-

* In Dr. Hunter's collection was an instance of above a thousand in one gall-bladder.

† As these calculi were voided by stool, their origin may seem somewhat doubtful.

porated spontaneously it is deposited from its solution in alcohol in white acicular crystals. It reddens litmus paper, and neutralizes the alkaline bases, and hence is an acid.

Cholesterine has been found in parts of the body wholly unconnected with the hepatic circulation, and from these facts it would seem to be a product of morbid vascular action under peculiar circumstances. Breschet found it in cancer of the intestines, and in the fluid of hydrocele and of ascites. Caventou found it in an abscess of the jaw, produced by a carious tooth. Christison found it in an osseous cyst of the kidneys, and in the membranes of the brain in epilepsy.

The bile of the human subject is liable to become diseased. In some cases, if tasted, it produces no other inconvenience than bitterness and a nauseous sensation; but in others, it will produce pustular affections, ulcers, and all the acridity which belongs to the most powerful agents of this class upon the tongue and lips. This must be owing to the bile having acquired some acrimonious properties, derived, no doubt, from certain morbid changes in its chemical constitution. The sensible changes exist in its colour and consistence: thus it presents every shade, from the deepest and most intense black to a nearly white tint. Its consistence is sometimes that of pure water; in other cases it is like pitch; and in others like glue or thick mucilage.

The chemical composition varies, as well as the relative quantity of the constituents. In some cases there is a considerable predominance of the resinous principle; in some there is an excess of the yellow, while in others the cholesterine is the superabundant principle. In some cases it has consisted almost entirely of albumen and water, and this has been observed more especially in connection with a fatty state of the liver. It may be observed generally, however, that little has been as yet ascertained as to the causes of these alterations. It is this alteration in the proportions of the constituents which gives rise to the formation of biliary calculi. They consist of the inspissated bile; of its resinous matter; of cholesterine; of picromel; and of the phosphates. Calculi are never found of any one of these principles solely, but some one or other predominates, giving the character. They may, by obstructing the regular course of the bile, cause its absorption, and thus give rise to jaundice.

Such are the anatomical characters and general nature of the principal organic diseases of the liver. We shall now proceed to their symptomatology.

Symptoms.—Perhaps there is no order of organic diseases in the whole human frame in which symptoms assist less than in that under consideration. In some of the more acute forms of disease the symptoms are urgent; but, except in a few instances, they convey little or no information with respect to the nature or progress of the disease; and in the more chronic and obscure forms, irreparable mischief is often established before the patient even suspects that there is anything wrong.

Many of these diseases, and indeed all of them in particular cases, produce certain constitutional symptoms, which, taken into account with the local ones, should any be present, will enable us to suspect, indeed confirm us in the belief of the existence of some sort of hepatic disease. But most commonly we obtain no farther instruction, and the real or precise nature of the disease remains in obscurity. We have nothing to do with inflammatory affections here: they have been already considered. But as hyperæmia may be accompanied with considerable enlargement of the organ, it will always be right in all suspected cases to examine the region of the liver, and ascertain whether any indication can be drawn from it.

When it extends or projects considerably below the ribs, it can, unless some obstacle exist, be felt, and its size pretty accurately determined; but in cases of ascites there may be considerable difficulty. The writer has often found the following plan succeed:—Place the hand upon the right side of the abdomen, and make the patient suddenly turn upon his belly inclining upon the right side; the enlarged liver will gradually sink through the fluid, and striking the parietes, will communicate a distinct impulse to the hand. Although this, should it occur, at once indicates the projection of the liver and the probability of its enlargement, yet the absence of this sign does not infer the converse, nor preclude the possibility of enlargement. Adhesions, for instance, by tying down the liver, will prevent the floating motion essential to the development of this sign.

Percussion often enables us to determine the height, or rather the encroachments, made by the liver upon the capacity or boundaries of the thorax. By this means the margin of the liver may be completely and accurately defined, and a tolerably accurate idea formed of its volume and extent.

There are no peculiar symptoms which will enable us to determine the presence of *anæmia* of the liver. *Induration and softening* may in particular cases be determined by the touch. *Hypertrophy and atrophy* may be discovered,—the former by the great increase of volume evident to the touch; the latter by the diminution ascertained by percussion. With respect to hypertrophy, it may be observed that there is no accurate means of diagnosis between it and hyperæmia. *Tubercles* may be felt in very thin persons, and if situated anteriorly; but there is no symptom peculiarly characteristic of them. The other diseases afford no symptoms by which they may be distinguished. Even gall-stones, unless passed by stool, afford no symptom by which their existence can be positively determined. Gall-stones passing through the ducts very often excite excruciating pain, cramps, sickness, vomiting, hiccup, &c.; but these symptoms indicate but little while they last; and more frequently it is after the passage of the stone, and after the subsidence of the symptoms, that we are able to form some opinion as to their nature and cause.

There are, however, certain general symptoms, which, when present, enable us to pronounce pretty positively as to the existence of hepatic disease, though they will not assist in determining its nature. These are dropsy, certain forms of indigestion, and jaundice; subjects already fully treated of in different parts of this work.

Other functions, as the respiration, circulation, those of the tongue, skin, and urinary apparatus, —the last especially, become deranged. The respiration and circulation merely present the common indications of irritation—a hurried or accelerated action. The tongue is generally coated, and commonly furred. A disagreeable taste is felt in the mouth, and eructations take place. What is brought up by eructation exerts various effects. Sometimes it is bitter, cutting, acrid, even excoriating the lining of the pharynx. This in general depends upon over-acidity, or upon chlorine. The fur on the tongue is yellow; sometimes moist, sometimes dry; sometimes permanent, and in some cases it appears only in the morning, disappearing in the course of the day. The skin may be hot and dry, parched and rough; or it may be too relaxed, giving rise to cold clammy sweats.

There is no excretion, not even excepting the alvine evacuations, which is more frequently deranged in the diseases of the liver than the urine. Thus, bile may be detected in the urine when no other irregularity is present, by the application of muriatic acid; it is sometimes necessary to concentrate it by slow evaporation, when the addition of muriatic acid strikes a green colour.

But organic disease of the liver is almost always attended with a deposition of the lithate of ammonia from the urine on cooling, of a bright pink colour. It receives this colour from the generation and intermixture of purpurate of ammonia. The urine when passed, though of a deep pinkish colour, is generally clear and transparent; but on cooling, the pink sediment separates; and if collected upon the filter and examined while moist, exhibits a remarkably deep pink colour. This sediment is re-dissolved by heating the urine.

The urine, after filtration so as to separate the sediment, likewise presents a deep colour, owing to retaining a portion of the purpurate of ammonia in solution. In some cases the urine will remain of a deep pink colour, nor will any sediment separate. This arises from a deficiency of lithic acid. The purpurate of ammonia has a strong tendency to combine with lithate of ammonia, which latter, being rather insoluble at the ordinary temperature, precipitates on the cooling of the urine, carrying down the purpurate along with it. But if there be a deficiency of lithic acid, no lithate of ammonia can be formed, and consequently no precipitate will take place. Hence the purpurate remains in solution, and gives this very deep pink colour to the urine, and which remains on the cooling of the urine without the formation of any precipitate. (Vide Prout, p. 125.) "The most perfect specimens of this kind of sediment which I have ever seen," says Prout, "were obtained from the urine of dropsical individuals; they occur also, occasionally, in the urine of the hectic, and of those obviously labouring under certain chronic visceral affections, *especially of the liver.*" (Prout, loc. cit.)

Such are the circumstances which individually and conjointly may be considered as furnishing tolerably certain indications of an hepatic affection; but it is only from the combination of several of these together that we can form any estimate of the degree or extent of hepatic disease. It must be evident, however, that we possess no certain or unequivocal means of determining the nature of the morbid condition with which we have to contend. And, indeed, even if we could, in the present state of our therapeutical knowledge, it would afford no guide to the adoption of any special mode of treatment.

Treatment. — In considering the treatment applicable to the organic affections of the liver, it will be useful to arrange it under two heads—general and local; understanding by the first, those means which act on the system generally; and by the second, those which are supposed to act by some particular local derivation.

General Treatment. — The first of this order which naturally comes under consideration is bloodletting. As the general circulation not only frequently produces, but afterwards tends to keep up the state of hyperæmia, or one of irregular vascularity in the liver, the means of controlling this function naturally presents itself as the most effectual as well as the most powerful of affecting a condition depending upon it. There are several points of view, however, in relation to different objects, in which bleeding may be considered. If the substance, or rather the vessels of the liver be gorged, bleeding generally, according to the circumstances, will be advisable. This means, also, will be applicable in what may be termed congestion, in which the capillary trunks are distended. Bleeding acts, not by abstracting blood from the distended organ, but by reducing the force of the circulation—the vis à tergo, as it is called—and, consequently, lessening the quantity of blood directed to the part, as well as the impetus with which it is driven.

An active state of the bowels will also prove beneficial; and the choice of the purgative will often be a consideration of some moment. When the object is to prevent the irritation arising from fæcal accumulations, those purgatives should be selected which merely excite the bowels to propel their contents; these are rhubarb, aloes, colocynth, &c. But when there is an active state of circulation, with symptoms denoting any thing approaching to an inflammatory condition, the purgatives which produce watery discharges are found the most serviceable. In such cases the neutral salts, largely diluted and combined with a small quantity of tartar-emetic, are the most powerful remedies.

When the disease is a simple hyperæmia, and has not produced any considerable tumefaction, a short perseverance in the above means will often be found adequate to all the urgencies of the case.

Emetics are not indicated in organic diseases of the liver, although nauseating remedies, by the power which they exert upon the circulation, are well adapted to reduce its force in the phlogistic diathesis. But emetics are occasionally useful when the functions of the stomach have been involved. In cases of this description, the stomach becomes overloaded with a collection of foul, crude, acrimonious matter, which proves highly irritating to that viscus, and by its reaction disturbs the system at large, and often aggravates the disease of the liver. When indicated, the mildest in operation of this class are to be preferred, and the

practitioner will find ipecacuanha most suited to his purpose.

It should never be lost sight of that lingering diseases are highly debilitating, and that emetics also exert a debilitating agency; and, therefore, caution is necessary in their use, and more especially in their repetition. The more mildly and the more speedily an emetic operation is effected and terminated, the less its debilitating effects; consequently, means calculated to effect such an object will be beneficial. The most effectual method of ensuring this, according to the writer's experience, consists in the previous ingestion of a considerable quantity of warm water; the advantages of which are, that a much less dose operates; there is no retching, nor are there any of those abortive efforts to evacuate the stomach which prove so distressing and so debilitating to weakly patients; and the stomach being emptied of its contents, there is an end to all the involuntary exertions of the patient.

Sudorifics are only admissible where there is considerable inflammatory excitement, with a harsh dry state of skin. In such cases those medicines which determine to the surface and induce a relaxation of the skin will prove highly beneficial. The most efficacious of this class is antimony; and the preparation must be selected according to the circumstances of the case. Tartar-emetic, in small and nauseating doses, not only relaxes the skin, but at the same time reduces the vital powers and prostrates the strength; while James's or antimonial powder effects the first object without influencing to so great an extent the strength of the patient.

Under the head of corroborants or tonics may be included two orders of remedies—stimulants and restoratives. The first are inadmissible in almost any description of organic disease; and, indeed, those of the viscus under consideration are often attributable solely to a too free indulgence in the use of stimulants. Restoratives, however, are of a different nature, and they are such as are calculated to improve the health and to give to the organs their due activity. The two most important of this description are sarsaparilla and taraxacum.

Sarsaparilla certainly at one time attained a high reputation as a restorative, owing, probably, to its being resorted to immediately upon the breaking up of the health by a too free use of mercury. Much of the good under such circumstances having arisen from laying aside the mineral, practitioners were disappointed in its powers, having anticipated too much from it in cases of a different nature, and, as mostly happens, not only refused to allow the virtues thus inconsiderately assigned to it, but denied even those to which it has unquestionably a claim. Hence it was nearly proscribed, and its use, in fact, almost laid aside. However, sarsaparilla certainly has considerable powers as a restorative, and will be found eminently useful in fortifying the system, and in preparing it for more active remedies. Dr. Philip observes that sarsaparilla is highly useful in protracted cases of indigestion, and especially "where the languor of the secreting surfaces has become permanent." (On Indigestion, p. 203. See, also, p. 258.) It may be administered in the form of decoction or of extract, or, what is still preferable, the extract rubbed down in the compound decoction.

Taraxacum is also a remedy which has been extolled, and it certainly seems in many instances to exert a very beneficial influence. According to Dr. Philip, it not only assists the use of mercury, but may, under certain circumstances, be substituted for it. (Ibid. p. 221.) But he asserts, that to be beneficial it must be given in large quantity, which often oppresses. The writer of this article has often found it a very useful plan to combine the extract of dandelion with the decoction of sarsaparilla, in which way—that is, rubbed down with the decoction—it can be given in much larger doses, and to a much greater extent, with much less inconvenience than simply in the form of extract.

The mineral acids are tonic and restorative; the principal of these are the sulphuric and the muriatic. They will be found highly useful in those passive relaxations of the skin attended by profuse night-sweats. The sulphuric acid is the most powerful in these cases.

It often occurs, however, that in these cases the bowels are constipated; and the profuse discharge by the skin may be considered as a vicarious, though morbid, substitute for that of the bowels. If the sulphuric acid should check the discharge by the skin without exciting the bowels, it will aggravate the symptoms. The plan most effectual in such cases is the exhibition of the bisulphate of potass or of soda, according to either of the following formulæ;—R. Infus. ros. ʒx; bisulph. pot. ʒii; syrup. caryoph. ʒi; *m.* fiat haustus ter quaterve in die sumendus.—R. Infus, caryoph. ʒx; sodæ bisulph, ʒiss; syrup. zingib. ʒi; *m.* fiat haustus ter quaterve in die sumendus.

The nitric, and a combination of the nitric with the muriatic acid—nitro-muriatic acid—have been supposed to exert a special influence upon the liver. The nitro-muriatic acid has been supposed to act through the chlorine disengaged by the reaction of some of the constituents. Special virtues, however, have been denied, and the flow of bile attendant upon their application as a bath, ascribed to the action of a weak or diluted acid upon the skin. (*Paris*, Pharmacologia et aliis locis.) A solution of chlorine, however, in water, according to the experience of the writer, has some claim to specific agency, and will be well suited to the class of diseases under consideration. It may be prepared readily by passing a current of chlorine gas into distilled water, kept cold by being surrounded with ice, and in a dark place, as chlorine under exposure to light decomposes a portion of the water, and muriatic acid is formed. The chlorine may be readily degenerated by exposing either a mixture of muriatic acid and peroxide of manganese, or of common salt, peroxide of manganese, and sulphuric acid, to a gentle heat in a proper gas bottle fitted with a tube for conducting the evolved chlorine into the distilled water.* The solution thus prepared may be given in small doses, at intervals during the day; and we have in many very severe cases seen the best effects result from this plan. The effects are

* It should be conducted into the water, and retained in it by a due degree of pressure.

healthy discharges from the bowels, bracing the skin, improving digestion, and correcting the secretions, and not unfrequently a considerable reduction of the pain and swelling of the epigastrium and right hypochondrium.

The powers of chlorine are frequently enhanced by colchicum, and it will often happen that a combination of these two remedies produces beneficial results which cannot be obtained by either separately. The preparation best adapted to the present object, is either the vinegar or tincture. In habits which show a tendency to gout or rheumatism, and in which temperaments, in the advanced stages of organic diseases of the liver, hemorrhages of various descriptions are apt to occur, colchicum proves a valuable auxiliary, and therefore should be administered.

It may happen, from some peculiar nervous idiosyncrasy, or from extreme susceptibility of the alimentary tube, that any of these means will produce severe effects, purging for example, followed by extreme prostration. Such must be corrected by the exhibition of appropriate remedies. Opium naturally presents itself; but in many cases there will be found strong objection to the use of opium. The salts of morphia are in many cases less objectionable, and as they do not produce the disturbance so frequently caused by opium, they ought perhaps, as a general rule, to be preferred. The most suitable of the above salts are the sulphate and the muriate, and the writer has been in the habit of using a formula analogous to that of Dover's powder. It consists of one part of the muriate or sulphate of morphia, two of ipecacuanha, and eight of neutral alkaline salt—sulphate of potass or muriate of soda. This powder may be given in small doses, or it may be formed into pills with extract of hyoscyamus or conium. The advantages, according to the writer's experience, are, that it does not affect or suppress the natural secretions so much or so certainly as opium, and consequently is not so likely to give rise to fever, with thirst, dry tongue, and hard pulse, which should always be most carefully avoided.

The means just detailed, are calculated to make but a slight impression upon an organically diseased liver. Tumefaction, hypertrophy, &c. may in slight cases be removed; but more commonly, very little impression can be made upon the seat of the disorder. The object, therefore, is rather to improve the health, and to fortify the system so as to enable it to endure the debilitating effects of more active and more powerful remedies, which may now be considered.

The efficacy of mercury in the treatment of the disorders of the liver is well known. It is the remedy to which all resort; and, as it frequently occurs in the exhibitions of medicines without principle, the prescriber is often doomed to experience disappointment. The first thing to be considered is, what is the action of mercury upon which we depend, and what the system to which we ought to direct its action for the relief of organic disease.

One of the principal effects of mercury is to excite the absorbent system; and it is upon this action that the practitioner must rely for its efficacy in diseases of the liver. The diseases of this organ, too, partake mostly of the congestive character, in which the vessels become distended with their natural contents, and consolidate from a degree of stagnation. This effect of defective or suppressed circulation is very perfectly shown in the consequences of peripneumony, in which we first perceive engouement—a gorged condition of the vessels, with impeded circulation terminating in consolidation—hepatization, as it is termed, of the lung. Mercury, by acting on the absorbent system, causes or rather promotes the removal of the solidified mass. But mercury likewise promotes or excites the activity of the circulating vessels. This is indicated by various phenomena —the fever induced by the mercurial action, the hardening, quickening, with frequency of the pulse. Therefore mercury appears to give an impulse to the circulation, and in all probability promotes the action and functions of the extreme vessels; consequently it excites their contractile powers, and thus enables them to force forward their contents. This appears to be the principle upon which mercury acts in removing such morbid conditions.

To ensure such results, we next inquire in what way the remedy should be given, or under what circumstances will such an effect be produced. The mercury must accumulate and produce its specific effects in the system. Hence it must not be suffered to pass off by the bowels; but it must be exhibited in such a manner as will ensure its accumulation without either purging or great irritation, which latter, by its reaction on the circulation, will tend greatly to increase the mischief and aggravate all the symptoms.

There are several modes of introducing mercury into the system; the principal are inunction, fumigation, and its internal exhibition. Inunction is frequently practised in liver affections, and was often considered the preferable mode; the remedy being applied in the neighbourhood, was supposed to pass into the organ; a principle which, even if well founded, would confer no particular benefit. The advantages occasionally derived from inunction, are referable rather to the friction than to the medication, the ointment merely serving to diminish the irritation from friction. Therefore, the circumstances which would lead the practitioner to prefer inunction or friction, are a peculiar irritability of the stomach and digestive tube, and a morbid sensibility to the local influence of the remedy. This is sometimes considerable, and frequently a source of great embarrassment to the practitioner.

Fumigation is applicable when the object is to bring the system under the influence of mercury in the least possible space of time.

The internal exhibition of mercury, however, is that upon which practitioners mostly depend; and it should be continued till its specific effects appear in a slight tenderness and tumefaction of the gums. Various preparations of mercury are resorted to for this purpose, and it may perhaps be useful to consider concisely the pretensions of the most active.

The preparations of mercury in most repute, are calomel and blue pill; the former is the more active but irritating, the latter the milder but more oppressive to the stomach. In some constitutions at all times, and in some only under particular

circumstances, calomel so irritates the stomach and bowels as to do much more harm than good. It is possible occasionally to correct this tendency by combination with a narcotic, as extract of henbane, hemlock, or Dover's powder, which last not only corrects the irritability of the bowels, but also favours the entrance of the mineral into the system. If, notwithstanding all these precautions, this preparation should irritate, some other formula must be substituted. The oppressive action of blue pill arises from the sugar and the vegetable matter of the confection of roses, and the fibrous matter of the liquorice-root used in its preparation; its comparative inertness, upon the large proportion of the metal which escapes oxidation. Blue pill, however, will often answer the purpose, and prove even sufficiently active when calomel could not be administered.

The stomach may be strengthened so as to resist the irritating action of calomel, or the oppressive influence of blue pill, by exhibiting a mild tonic or aromatic draught about an hour before giving the mercury. The writer has found the infusion of cloves with the aromatic spirit of ammonia the most effectual for this purpose.

We have frequently found it an efficient practice to resort to the grey or protoxide of mercury. This is uniform in strength, and is not necessarily, as in the preparation of the blue pill, combined with agents which exert an oppressive action upon the stomach. The requisite dose may be combined with extract of hyoscyamus, or any other similar extract, or it may be given in powder. It is asserted by Dr. Barker, that a portion of the protoxide is apt to pass to the state of peroxide. The contamination, however, probably results from original impurity. The London College direct it to be prepared by the action of lime-water upon calomel; and as calomel is occasionally contaminated with oxymuriate, of course in such cases there will be an intermixture of peroxide. The best way of preparing protoxide of mercury is to form a proto-nitrate by the action of diluted nitric acid unaided by heat, and then precipitating by means of potass, and washing the precipitate. The protoxide thus prepared gives no indication of peroxide, even when kept for a considerable time.

Other preparations of mercury have been used, as the oxymuriate, but this is not generally the best for employment, although the writer has met with many instances in which it superseded all the other preparations. In general, the best way of giving it is with the decoction of sarsaparilla.

The acetate and the phosphates of mercury are very active preparations, and agree very well with the stomach. The advantages of the latter preparations are that much smaller doses answer, an object of moment when the stomach is apt to be oppressed; and in the case of the acetate, the readiness with which its acid is decomposed in the stomach or in the system, and the mineral introduced.

Sometimes the irritation arising from mercury, depends upon the existence of a free acid, or perhaps free chlorine in the stomach. In such cases not only is the sensibility of the mucous lining morbidly acute, but a more irritating preparation is formed. This may be corrected by some absorbent earth, as chalk, lime, magnesia, or an alkali; and this probably will explain the advantages experienced by the writer, and mentioned in a preceding column, from exhibiting spirit of ammonia in infusion of cloves, before taking the mercurial. In similar cases, the hydrargyrum cum cretâ, or with magnesia,* will frequently answer the purpose: but the most certain plan consists in giving the absorbent an hour or so before the mercurial.

Many years since it occurred to the writer that the powers of mercury might be greatly enhanced by combination with iodine, in accordance with an acknowledged rule or principle in pharmacology, that the virtues of remedies exerting singly a similar specific agency, would be greatly increased by combination; and the preparation of the proto- and deuto-iodurets of mercury† were consequently administered in various tumours and enlargements; such as bronchocele, hepatic and other visceral enlargements, and indeed all descriptions of abdominal swellings. The results were highly satisfactory. One or two cases even of white swelling and hip-joint disease perfectly recovered by the use of the iodurets of mercury with the means to be presently detailed. It is, however, in glandular swellings and in the vascular congestions of parenchymatous structures, and the consecutive organic changes which these structures undergo, that this combination is most effectual. In a treatise on organic disease, printed in 1824, we have entered fully upon this subject and the different objects to be kept in view.

More recently we have had some opportunities of again proving the efficacy of this preparation. A young woman in the country began to swell about the abdomen, and was considered pregnant by her medical attendant. She came to town, and a medical friend was requested to attend her in her accouchement. He, however, doubted the pregnancy, and her time having elapsed without any diminution of size, calomel and hydriodate of potass were given, and an abdominal swelling of nearly eleven months' duration, and which confined the patient to bed for more than two months, was reduced in about three weeks, and the patient restored to perfect health. A second instance occurred in the practice of another medical friend. It was an abdominal swelling, probably of an ovarian description. We recommended the plan pursued in the last case. It was, however, some time before it could be put into execution, and the swelling remained unabated. At last, however, it was adopted, and in about three or four weeks the abdomen was reduced to its natural size. This patient, however, died, (the constitution having been completely broken up by previous dissipation,) but on examination no indication whatever could

* To these preparations the same objections apply as to blue pill — namely, the partial or imperfect oxidation of the metal. The grey or protoxide prepared as above, and mixed with the chalk or magnesia, (the latter preferable,) will be found the preferable formulæ for exhibition.

† The proto- and deuto-iodurets of mercury may be prepared extemporaneously, by mixing calomel or oxymuriate of mercury with the equivalent of hydriodate of potass; an interchange of principles takes place even in the dry way. It is, of course, intermixed with muriate of potass, which might be washed out if it were of importance to free the preparation from such an impurity.

be traced of the part which had been enlarged. One ovary, probably the diseased one, had entirely disappeared.

The iodurets affect the mouth in the same way as the more ordinary preparations of this mineral. They may be given in similar doses, and the deutoioduret in larger doses than the oxymuriate. They may also be introduced by friction; but the deutoioduret almost always produces a bright scarlet efflorescence of the skin, which mostly terminates in desquamation. The precautions as to correctives, when considering mercury generally, are equally applicable to the iodurets.

Some constitutions powerfully resist the mercurial action; such stubborn resistance is to be overcome, in plethoric habits, by bleeding, by nauseating doses of emetics, by opiates, and other well-known means. The introduction of mercury also is often attended with a febrile irritation or excitement, which, reacting on the diseased viscus, counteracts whatever benefit might otherwise be obtained. This must be kept in subjection by bleeding and other antiphlogistic measures, and by local measures which will also prove auxiliary upon other principles.

The affections which will be benefited by this plan are hyperæmia of every description, hypertrophy and all sorts of enlargement, induration, scirrhus, tubercular conditions, even the scrofulous, and most adventitious deposits, excepting the osseous, and even this perhaps if incipient. Its efficacy is questionable in abscess, ulceration, and cancer; but still it may be likewise questioned whether the iodurets should be wholly proscribed in such affections were we satisfied of their existence. It is not improbable that if the absorption of the diseased structure were effected, healthy deposition might be substituted in its stead.

It may be inquired for what length of time the mercurial preparations should be continued. Mercury, it has been already observed, not only excites a febrile irritation, but also exerts a noxious influence upon the economy at large, and this influence is directly as the quantity and its effects. Therefore, the object is to induce the specific effects with as little irritation as possible, and with the least possible quantum of the mineral. But in many instances the effects having been induced, the mercury must be laid aside, and the disease will remain stationary; and the practitioner must again and again have recourse to the remedy. Each succeeding application to mercury is attended with severer consequences, and it often happens that on the subsidence of the organic affection the patient finds it effected only by a total breaking up of the constitution, and a fatal sacrifice of health. The debilitating or rather exhausting effects of mercurial courses are too generally understood to need any comments in this place. Upon reviewing these facts it occurred to the writer that the good effects resulting from the iodurets of mercury might be kept up and a beneficial influence exerted on the disease by some other of the metallic iodurets. With this view, upon the first indication of the mercurial influence, whether the development of the specific influence upon the gums, or a reduction of the disease, the ioduret of iron or of zinc was given, or the hydriodates of these metals in solution. The result was extremely satisfactory; and morbid conditions which had been but slightly affected by the mercurial iodurets were completely dispersed under the ioduret of iron or of zinc. These preparations will be found much better adapted to weakly, irritable, and leuco-phlegmatic habits. Of these two the ioduret of iron is perhaps the most irritating and inflammatory, that of zinc the least so. They may be given either in pills, or in solution, as hydriodates, readily by mixing a solution of the equivalent of sulphate of iron or of zinc with one of hydriodate of potass; an interchange of principles and the formation of the new salts, hydriodate of iron or zinc, is the result.* Whatever objections may offer to the employment of the mercurial iodurets in cancerous, scrofulous, and other cachectic diseases of the liver, none such can be urged against those of iron and zinc, and therefore, the practitioner may safely appeal to them under the assurance that he is not employing a destructive or injurious remedy. The doses of these salts must be regulated in a great measure by their effects. From one grain to ten, according to circumstances, may be given three or four times a day; the practitioner recollecting that the smallest doses should be tried at first. Another circumstance to be attended to is that the system becomes blunted by habituation to a remedy. Increasing the dose is often carried to an extreme without benefit, and frequently not without injury. The susceptibility cannot be kept up by over-doses, but when dormant it may be awakened by a temporary suspension of the medicine. Thus, when the average extent of dose fails to produce its accustomed effects, the medicine should be laid aside for a time; and when a respite has been thus granted to the system, we shall find all its sensibility restored, and we may again resort to our means, confident of finding the usual susceptibility to impression.

The state of the urine has been noticed in a previous part of this article, and an examination of it will often afford useful information. There are two conditions of it, however, which deserve attention in hepatic diseases, namely, an excess of urea, and its ready coagulation by heat. This latter property arises from albumen or chyle, and is often present in the dropsies consequent upon hepatic disorder. It may be laid down generally that such conditions forbid any active use of mercury. It betokens a state of system altogether hostile to the use of this mineral. But the metallic iodurets just considered, according to the writer's experience, are not liable to the same inconveniences.

During the pursuance of all the above means, it will be necessary to attend not only to all the functions, but to the conditions of the organs which perform them. When we find urea in excess, or the curdy coagulation depending on the presence of chyle, there exists an irritability of system which must be soothed by morphia, hyoscyamus, and the acetic extract of colchicum, which will be found a most valuable auxiliary under such circumstances. The denser coagulation arising from albumen indicates not only irritability, but an excitability of the phlogistic character, which must be subdued by venesection (especially if

* In this case sulphate of potass remains in the mixture, but the impurity is of no moment.

attended with local pain) and other suitable modes of evacuation. It is almost unnecessary to observe that the digestive functions should be closely watched, and the condition of the organs attended to, and any degree of aberration immediately corrected. Hence the advantage of occasional stomachics, &c. Should the disorders of organs secondarily affected remain unheeded, they will soon, by their reaction, aggravate all the symptoms of the primary disease.

Local Means.—While the practitioner is endeavouring to subdue disease by what are termed general means, he should frequently examine the region or seat of the diseases. This will in many cases be found swelled, painfully sore or tender. These states are to be relieved by those means which directly deplete the part itself. Leeches therefore should be applied: and it is often useful to repeat the leeches at regular intervals, that is, every three days, every week, every fortnight, &c., according to the extent or severity of the pain or tenderness.

It is often useful to alternate leeches and blisters, and the most surprising improvement frequently results from this practice. In some cases, however, blisters alone prove most serviceable, leeches only debilitating and distressing the patient, and in others the converse of this will prove the case. It is almost impossible to determine, *à priori*, which of the two plans or whether a union of both will be found the most effectual.

Various plasters which excite or irritate the skin sometimes do good, when neither leeches nor blisters can be endured. Burgundy pitch is of this description; but the most effectual is the "emplastrum ammoniæ,"—a combination of muriate of ammonia and soap, in which the alkali gradually abstracting the acid, the ammonia is disengaged, and applied in its escape to the skin, which produces a beneficial irritation. It should, however, be applied immediately on its preparation, and to insure fully its beneficial effects it should be frequently renewed.

Of all the local means, however, there is nothing equal to a perpetual drain in those chronic conditions termed organic disease. Setons and issues are not so often resorted to as their remedial efficacy would lead us to expect. Organic disease is a result accomplished by a very slow and gradual process, and is not, like acute disease, to be immediately suppressed or removed. The constant drain effected by an issue from the general system will also greatly tend to keep down febrile excitement, which it is well known greatly aggravates local disease of every description. A caustic issue, therefore, which is perhaps the most convenient and the most manageable, should be inserted in the region of the diseased viscus; and its exact position and extent should be regulated by the nature, extent, and severity of the tenderness.

The effects of setons, issues, &c., are slow, though progressive, and sometimes a depression of strength supervenes during the continued action of the permanent drain. This proves as embarrassing to the physician as distressing to the patient. In such cases a little more generous diet must be allowed, and mild, unirritating tonics administered; and if the loss of strength prove extreme, the issue must be dried up for a time, or the discharge reduced by the removal of an adequate proportion of the peas.

When we find it necessary to heal the issue, and at the same time to support the strength by tonics, in certain temperaments of the nervo-sanguineous character, languid inflammatory action is apt to be excited. This is best kept down by occasional cupping, leeches, &c. Where even so small a loss of blood seems prejudicial, the best effects result from dry cupping, repeated at short intervals. Dry cupping often proves the most effectual remedy in some forms of hyperæmia and engouement, and its effects upon the accompanying tumefaction are as surprising as they are inexplicable.

Organic diseases of the liver induce a train of consequences both severe and troublesome. The functions and structure of other parts become deeply engaged; and hence dyspepsia, dropsies, apoplexies, and inflammatory affections. In all cases, the complication must be attended to, and, as far as possible, its reaction on the system at large, and on the primary affection counteracted. The means of accomplishing this consist in those peculiarly adapted to the removal of the secondary disease itself, modified, however, by the existing circumstances. The practitioner, however, must be prepared for a tedious disease, and he must not relax in his endeavours, nor give up in despair, if the amendment should not keep pace with his wishes.

R. Venables.

Liver, Inflammation of the. Hepatitis, from Lat. *hepar*, Gr. ἧπαρ, *the liver*.

The history and symptoms of inflammations of the liver have been peculiarly dwelt on in all works on medicine, from the earliest periods. In fact, until very recent times, when the attention of physicians was more especially called to the diseases of the gastro-intestinal mucous membrane,—heretofore a comparatively unexplored field,—this affection and its subsidiary diseases were more studied than any other lesion of the digestive apparatus. (See Gastro-Enteritis.)

Pathology.—The liver may labour under the effects of increased quantity of blood in its parenchyma, from several causes. Of these, the two most important are—1. *active congestion*, the result of irritation in its tissue, either primary, or the consequence of some other lesion originating in its own substance, or some other organ with which it sympathizes; and 2. *passive congestion*, induced by mechanical obstruction to the exit of its venous blood. This obstruction may be seated in the hepatic veins, the heart, lungs, or even in the aorta, (*mechanical hyperæmia of Andral.*) In addition to these, two other sources of congestion are mentioned; one a stasis of blood, similar to that which occurs in organs attacked with scorbutic disease, and the other the congestion which occurs so remarkably in intermittent fever; a congestion sometimes so intense as to induce hepatic apoplexy.*

The results of inflammatory action on the liver vary according to the intensity, length of duration, and situation of the disease. In general, the first

* *Bailly*, Traité anatomico-pathologique des fièvres intermittentes, simples, et pernicieuses, 1825. See, also Mackintosh, Cleghorn, &c.

visible effect is the production of increased vascularity of the parenchyma, which may be either general or partial; but we believe that in the majority of cases the latter is most frequent. This is accompanied with tumefaction of the part, and is the first stage of acute inflammation, as far as this can be demonstrated by the knife: under these circumstances the hepatic tissue is extremely red, and blood flows copiously when it is divided by the scalpel.

In a still more advanced stage, in addition to the vascularity, we observe a remarkable softening of the part, sometimes so great that a slight pressure will reduce it to a mere pulp. This stage is analogous to the second stage of acute pneumonia, and, like it, may be accompanied by the formation of pus or lymph on the serous surface. In this respect, however, there is a great difference between the liver and lung, as we seldom meet with pneumonia without serous inflammation, while the reverse often obtains in hepatitis. This is a point of great importance in the surgical treatment of the disease, and one to which we shall recur.

On this subject Mr. Annesley makes the following remarks:—"When the surfaces are the seat of inflammatory action, the internal structure of the organ generally participates in it to a greater or less extent, and likewise, when morbid vascular action commences in the parenchymatous structure, it sometimes extends to the external surface; but this more rarely occurs in India than the former mode of extension, the internal structure appearing to us to be more frequently the seat of the inflammatory state than the surfaces, which seldom participate in it till the more advanced stages of the disease. We frequently observe in India the internal structure of the liver inflamed to the greatest possible extent, without any effusion of lymph from its surfaces, and the inflammation of structure may go on to the production of several abscesses in both its lobes, or of one very large abscess in the eighth lobe only, without any decided marks of inflammation of the envelop of the organ, except some alterations of colour merely, which are usually occasioned by the states of the parts immediately underneath; nay, even abscesses of the liver may proceed to the utmost extent, and ultimately break into the abdominal cavity, without having induced inflammation of the serous surface where they point, and consequently without forming adhesions to the parts with which they are in immediate and close contact. (Annesley's Diseases of India, vol. i. p. 406.)

In the report of the Meath Hospital, by Dr. Graves and the writer of this article, (Dublin Hospital Reports, vol. v.) the important fact of the rarity of adhesions in cases of hepatitis, even after the formation of abscess, is noticed. This is a fact which we had observed long before the appearance of Mr. Annesley's work, and one from which it would appear that both in the warm and temperate climates acute inflammation of the liver is much more seldom complicated with serous inflammation than a similar state of the pulmonary parenchyma. It is not easy to explain this singular but most important difference; but it is obvious that the only mode of arriving at a solution of the difficulty is to compare the physiological relations of the two membranes.

It has been long admitted that the peritoneum is less liable to the adhesive inflammation than the pleura, as, in our examinations after death, we commonly meet with adhesions of the pleura, while those of the peritoneum are comparatively rare. This fact, however, may, to a certain degree, be explained by the greater fatality of abdominal inflammations, a greater portion recovering from pleuritis than from peritonitis. The more frequent affection of the pulmonary serous membrane in cases where the subjacent parenchyma is engaged, may be explained partly by the greater degree of motion which, in consequence of the function of respiration, the two pleural surfaces are exposed to; as in this way the parts are not only predisposed to inflammation, but a slight effusion of lymph may become an exciting cause of disease by its mechanical action over an extensive surface. Again,—if, as there is great reason to believe, the air-cells are in reality white tissues, the propagation of inflammation from them to a similar structure ought more readily to take place than from the glandular acini of the liver to an essentially different tissue.

The next stage of hepatic inflammation which has been described is that of purulent formation or abscess; but we believe that between this condition and the red softening of the liver there is an intermediate stage, in which the hepatic tissue is found of a yellow colour, exceedingly soft, and leaving a puriform exudation on the scalpel. Between this state and the third stage of pneumonia there appears to be a great analogy, as it is an interstitial suppuration immediately preceding the formation of abscess. In several instances we have observed this alteration to extend to some distance around an hepatic abscess, and in cases where numerous small purulent collections existed, the hepatic tissue which separated them had undergone this change. The tissue thus altered varies considerably in consistence, in some instances being almost semifluid, in others possessing a certain degree of firmness. As yet this condition does not appear to have been recognised in the systematic works on pathology.

Lallemand, in his "Lettres sur L'Encéphale," speaks of a softening of the liver, in which, in consequence of severe inflammation, its tissue is reduced into a diffluent sanies of the colour of wine-lees; but this condition is obviously different from that we have just described.

Abscess of the liver, so common in India, is of rare occurrence in these countries. A few isolated cases are to be met with in medical records, but no series of cases was published as occurring in Europe until the appearance of Louis's researches on this subject. (Recherches Anatomico-pathologiques. Paris, 1826.) Subsequently, the writer of this article, in conjunction with Dr. Graves, published several examples of this lesion. (Dublin Hospital Reports, vol. v.)

Puriform matter, as the result of inflammation, is met with in the liver under several forms. We may find it, as it were, infiltrated into the hepatic tissue, as described above,—a condition to which the name of yellow softening of the liver may be given; it may occur in numerous minute ab-

scesses; or, lastly, it may form one or more large collections of matter, in some cases encysted, in others bounded only by softened and yellow hepatic substance. These collections of matter are generally isolated, though in a few cases they have been found to communicate by fistulous passages.

As yet we are not fully aware of the circumstances which dispose to the formation of a cyst around these puriform collections. The more chronic the abscess, the greater will be the likelihood of a cyst existing, but it will often be found even in recent cases. We have seen these cysts under very opposite circumstances. Thus, in a case which occurred in the Meath Hospital, where, after acute hepatitis, the patient sank with suppuration of the liver, we found numerous abscesses, some the size of an orange, others that of a hazelnut, the smaller being encysted, the larger not so. In another case, however, the reverse of this was observed. A patient had laboured under gastro-enteric fever for some time, when attention was directed to his liver, from his complaining of pain in that situation. The organ was then found enlarged, and it soon became evident that matter was forming. The patient died, and on dissection, a vast abscess in the right lobe, capable of containing several pints, was discovered: this was encysted, while in the remainder of the liver were numerous small abscesses, only separated by softened hepatic tissue. In another case, the particulars of which we shall detail hereafter, a very chronic abscess, communicating with the duodenum, existed in the right lobe, while a recent one, which had opened into the peritoneal cavity, was found in the left. In the first abscess, which had existed under our observation for two months, we found the cavity empty, and lined with a strong semi-cartilaginous membrane, of a dark greyish colour; while in the second there was no cyst whatever, its parietes being formed of yellow softened hepatic tissue. The last case which we shall notice on this subject is that of a woman who sank under a very chronic abscess of the liver. Here the cavity was of enormous dimensions, and presented an imperfectly formed cyst, most developed where the parietes of the abscess were thinnest—that is to say, immediately under the serous covering of the convex surface. In the more deep-seated parts it could hardly be detected.

The appearances of structure of these cysts are various. In some cases we only observe a pseudo-membranous layer, of a line or two in thickness, yellowish white, and resembling semi-concrete pus. In other cases the cyst appears organized, and may strongly resemble a mucous membrane; presenting villosities more or less completely developed, which we can easily demonstrate by immersing the part in water. A third variety presents the lining membrane of a reticulated structure, for which the name of fibro-mucus has been proposed; while in the last species the membrane is semi-cartilaginous, of an iron-grey colour, and very similar to the investment of chronic tuberculous cavities in the lung.

Nothing can be more various than the size of these abscesses. We have seen them so large as to be capable of containing four pints, and, on the other hand, they may be so minute as to represent suppurated tubercles, from which indeed it is sometimes difficult to distinguish them. The surrounding hepatic tissue is generally in a state of red or yellow softening, but cases are on record where it has been found perfectly unaltered; in these the disease was generally chronic. The same variety is observable in the nature of their contents. In all our cases, but with one exception, the matter was healthy, though sometimes mixed with portions of softened hepatic substance. In the case of exception, in which the operation of opening the abscess was performed successfully, the matter was of a dirty green colour, and mixed with sanious fluid. Andral states that in all the cases in which he found puriform matter in the liver, it was white and consistent, like the pus of a phlegmon, and that those who have described it as similar in colour to the lees of wine have confounded other diseases, particularly the occurrence of encephaloid matter, with the inflammatory suppuration. In warm climates, however, great variety is observed in this respect. "The matter," says Mr. Annesley, "contained in an abscess presents various appearances. In some it is a thin, watery pus; in others, it is thin, watery, and with thick curd-like clots floating in it; in many cases it is perfectly purulent, and of varying degrees of consistence. As respects colour, there is also considerable difference; most frequently the matter is of the usual yellow colour. Sometimes it presents a yellowish-brown or sanious tinge, and occasionally a greenish-brown or greenish-yellow hue; sometimes it is watery or reddish brown; at other times it is observed of a creamy consistence, and nearly white. (Op. cit. p. 533.)

It is to be regretted that the relations which exist between the vessels of the organ and these collections of matter have not as yet been made the subject of any accurate investigation. We cannot find any instance recorded, where, as in tuberculous and other cavities in the lung, vessels were found traversing the puriform collections. They have been observed, however, forming projections on the internal surface of the cysts; but when we consider the vast size to which hepatic abscesses may attain, the inquiry as to what has become of the vessels becomes a matter of extreme interest, and in the present state of pathological anatomy offers a new field for inquiry.

The abscess once formed may open in a great variety of situations both internally and externally. Of the internal openings we have witnessed the following examples:—1. perforation of the diaphragm and communication with the lung; 2. communication with the duodenum; 3. perforation of the peritoneum, and effusion into the abdominal cavity.

The first of these terminations appears to be a not unfrequent and perhaps the most favourable of the internal openings of the abscess. Many patients have recovered where this lesion undoubtedly occurred, as indicated by the fact of their presenting all the symptoms of hepatic abscess, both constitutional and local, which subsided upon the occurrence of a sudden and copious expectoration of purulent matter, which had not been preceded by any symptoms of pulmonary disease. We have known of cases where pressure exercised on the hepatic region was immediately followed by a free expectoration of pus. The easy exit of

the purulent matter, the result of its entrance into the bronchial tubes, is in all probability a principal reason why this termination of the disease should be so often favourable. The abscess may open either into the right or left lung; and though there are some cases where the pulmonary pleura was not perforated, yet the communication with the pulmonary parenchyma and bronchial tubes is much more frequent than the formation of an empyema, — a circumstance explicable by the great tendency to adhesion presented by the pleura.

Dr. Smith, an American writer, details a case where the hepatic abscess opened into the pericardium. The liver, which was almost entirely occupied by an enormous abscess, adhered closely to the upper portion of the diaphragm, through which the opening between the abscess and the pericardium existed; the pericardium was inflamed, and contained about two pints of a purulent liquid similar to that which existed in the liver.

It would appear, then, with respect to the thorax, that the abscess may open into the lung, pleura, or pericardium. Of these, the first is by far the most frequent. With respect to the abdomen, the abscess may communicate with some portion of the gastro-intestinal tube, the peritoneal cavity, the gall-bladder, the vena cava, or kidney. In the cases where the opening has taken place into some portion of the digestive tube, its seat has been in the stomach, duodenum, or colon.

Lastly, the abscess may open externally in a great variety of situations upon the abdomen, and also on various places on the side and in the axilla. When the opening takes place externally, it is seldom by a direct, but commonly by a sinuous and fistulous passage. Louis, in his *Recherches Anatomico-Pathologiques*, declares that he has never yet known of the occurrence of a cicatrix in the liver, the result of a cured hepatic abscess. We feel satisfied that this is a pathological appearance rarely observed in the dissecting-room, — a circumstance to be explained by the rarity of the disease in this country and its general fatality. In one case, however, we have witnessed this rare appearance. A patient who had been a soldier in the East-India Company's service, and who had, while in India, suffered from an attack of hepatitis, accompanied, as he described, by great tumefaction of the liver, died in the Meath Hospital of a chronic enteritis. On dissection the right lobe of the liver was found greatly diminished in volume; while in the centre of its convex surface existed a very deep stellated depression, around which the hepatic tissue was puckered, rising in the form of crests with intervening sulci of nearly an inch deep. From the centre, which was occupied by a mass of cartilage nearly the size of a walnut, emanated prolongations of thin plates of cartilage, answering in number to and forming the base of the sulci which appeared on the surface. In this case we are not able to determine by what aperture the contents of the abscess had been evacuated, but in all probability it was through the duodenum. The appearances on dissection in this case were almost identical with those in a case of cicatrices of the liver, of which Mr. Annesley gives a beautiful drawing, (see plate 15 of his book.) This gentleman states that he has met with several cases of these cicatrices in India. There is a form of disease which is very liable to be confounded with hepatic abscess, as it has many symptoms in common with this affection; we allude to a circumscribed inflammation and suppuration in the parietes of the abdomen, immediately over the liver. The disease sets in with fever, pain, tumefaction, and tenderness in the affected part; and, in addition, we have many of the constitutional symptoms of hepatitis. In one case, which occurred in the Meath Hospital, a slight jaundice existed for several days, analogous, in all probability, to that arising from diaphragmatic pleurisy. These cases are generally of little severity as compared with true hepatitis. Matter forms speedily under the integuments, and, on this being evacuated, the patient rapidly recovers. In a case, however, which we have witnessed, the disease proved fatal under very remarkable circumstances; we shall therefore notice it at greater length. A woman aged twenty-three, who had laboured under amenorrhœa for twelve months previously, was attacked with cough and hemoptysis, followed, after some days, by fever, pains in the back and limbs, and prostration of strength. Soon after this she complained of pain in the right side of the chest and hypochondrium, increased by coughing, pressure, or motion. She had a distressing short cough, with yellow tenacious expectoration. The inferior portion of the right side of the chest sounded dull, and the respiration in this situation was almost inaudible except when she made a forced inspiration. The symptoms having continued for about a fortnight, an uncircumscribed puffy tumour made its appearance over the lateral portion of the liver; the hemoptysis returned, with a hard teasing cough, but the fever disappeared; poultices were diligently applied to the tumour, which rapidly enlarged and presented evidences of extensive suppuration. On the thirteenth day after its appearance it was opened by means of an abscess-lancet, when a great quantity of matter mixed with blood was discharged; at this time the spitting of blood ceased. In about three weeks, however, the abscess again appeared, and rapidly increased to a size much greater than its former dimensions; it was again opened, and a large quantity of purulent matter given exit to. On the next day the abscess presented the appearance of an enormous anthrax, with edges about two inches high, from which a quantity of whitish slough could be detached by pressure; the patient was now emaciated, had diarrhœa, with cough and sanguinolent and puriform expectoration. We endeavoured to trace the extent of the disease by introducing a probe; but although this was found to pass extensively under the muscles and cellular substance, yet it could not be introduced either into the thoracic or abdominal cavity. After some time it was found that when the patient coughed, or took a deep inspiration, air escaped with great violence from the base of the ulcer, towards the upper portion of which a circular fistula, through which a probe could be passed, was observed; through this the probe passed for about three inches, when it met with a solid resisting body. The inframammary region sounded clear on percussion. Examined by the stethoscope, the respiration was

cavernous, and accompanied during inspiration by a sound like the tick of a watch. When the patient coughed or made a forced inspiration, a loud guggling was audible. There was no metallic tinkling, *bourdonnement*, or pectoriloquism; but the voice resounded strongly from the sixth rib upwards, while anteriorly and posteriorly the respiratory murmur appeared natural. She died on the following day.

Dissection.—Great emaciation. The external sore extended from the sixth to the tenth rib: it was about four inches in breadth. Between the eighth and ninth ribs the fistula was plainly observable. On opening the abdomen, the serous membrane was found healthy, with the exception of that portion which covered the liver laterally and superiorly. Here the liver adhered to the diaphragm.

On the centre of the convex surface of the liver we found the base of the abscess formed by a circular portion of thick, false membrane, of about two inches in diameter, *external* to *the hepatic peritoneum*, but producing a depression on its surface. The costal portion of the diaphragm, for an extent corresponding to the base of the abscess, was destroyed, but adhered round its edges. This abscess communicated with the lung by a perforation through the diaphragm of about the same size as the external fistula, which led into an abscess in the lower lobe of the right lung. This was narrow, elongated upwards, and presented many of the characters of pneumonic abscess. It had no lining membrane, and communicated with numerous bronchial tubes. Around it the pulmonary tissue was of a greyish-white colour, softened but not granular. The diseased portion did not terminate by any distinct line, and occupied about two-thirds of the lower lobe, which was universally adherent to the diaphragm, and for about three inches to the costal pleura; the remainder of the lung was healthy. The mucous membrane of the stomach was pale and soft; the lower portion of the ileum red, and presenting some aphthous ulcerations: the mucous membrane of the colon was covered with fungous elevations, and numerous aphthous ulcerations. (Meath's Hospital Reports.)

In this case the diseased action had in all probability a double seat from an early period, namely, the lower portion of the lung and the integuments over the liver; it is remarkable for the double perforation of the diaphragm through its costal and thoracic portions, and for the direct communication made by the latter with the substance of the lung: the pleural and peritoneal adhesions prevented the escape of the matter either into the thoracic or abdominal cavity; a circumstance illustrative of the powers of nature in availing herself of diseased action to promote an ultimate cure.

Some authors have described gangrene as a result of hepatic inflammation; but facts are still wanting for the elucidation of this subject, and there can be but little doubt that, if it ever does occur, it must be a circumstance of extreme rarity. On this subject we shall quote from Mr. Annesley:—

"Gangrene has been remarked by many writers and teachers as one of the terminations of acute inflammation of the liver; but although we have observed this disease, and made post-mortem examinations of it, the number of which certainly has not been exceeded by any other inter-tropical practitioner, we have never seen a single case of gangrene of this viscus. We are inclined to believe that the appearances that have been taken for gangrene have been merely that black, congested and softened state of the organ which is sometimes observed in the more acute attacks of the disease, supervening to congestion, or at least this state of the viscus having speedily run into gangrene after the death of the patient; and therefore, if gangrene had actually existed at the time of dissection, it is to be considered as a consequence of death rather than a termination of the disease." (*Op. cit.* vol. i. p. 435.)

In the works of the modern pathological anatomists of Europe, the same infrequency of gangrene of the liver is observed; so that we may conclude that both in warm and temperate climates the termination of hepatitis by gangrene is of extreme rarity. Andral relates one decided case of gangrene of the liver, where the disease surrounded an abscess of the left lobe, and states that this is the only instance he has seen of gangrene of the liver. When we reflect on the vast number of dissections which this great pathologist has made, the fact of his having seen the disease but once is a decided proof of its rarity. Here is another circumstance in which the pathological relations of the liver differ remarkably from those of the lung, as, in the latter viscus, gangrene is a not unfrequent occurrence; but when we consider the greater liability to a stasis or effusion of blood in the pulmonary parenchyma, as compared with the hepatic, and also that in the lung the diseased portion is exposed to the action of air, we may find in these circumstances an explanation of the fact.

The effects of chronic inflammation on the liver are exceedingly various, and its results greatly influenced by the constitution or habit of the patient. Among them may be enumerated the different forms of hypertrophy, either partial or general, either of the red or white substance, or of both; induration; scirrhous or tuberculous tumours; and hydatids. We are far from believing that these latter lesions are always the result of an inflammatory process; as there is undoubted evidence that these new tissues may be the result of a lesion of secretion and nutrition, not induced by any previous irritation of the part; while, on the other hand, cases are on record where these different diseases appear to have been first brought about by an acute or chronic hepatitis. The following observations by Andral on this subject are highly philosophic:—

"There is scarcely one of the alterations of the liver which have been described which has not been designated by the name of hepatitis. In my opinion, there is hardly one of them which may not be the result of an irritation whose first effect was to cause an hyperæmia of the liver. For example, four individuals receive an external injury on the same region of the liver: in one an abscess is developed in the liver; in the second this organ becomes cancerous; in the third it becomes filled with hydatids; and in the fourth it

is atrophied. In all these four cases irritation has been manifestly the point of departure: but what has been its mode of action? It has deranged the normal nutrition of the organ; there its influence is confined: the predisposition of the individual has done the rest. On the other hand, I do not know an alteration of secretion or nutrition of the liver, not even a collection of pus in its parenchyma, that can be considered as necessarily arising from an antecedent process of irritation. I do not know one of which we can say that its formation has been necessarily preceded by a hyperæmia. What, then, does the word hepatitis express? Nothing more than the common link by which the different lesions of secretion and nutrition of the liver are often united. But this link is neither constant nor necessary; and if we have seen a case where an hyperæmia of the liver by external violence has been followed by the formation of hydatids, I may cite many other cases where nothing has demonstrated a similar point of departure, and where, from analogy, we would arrive at an opposite conclusion, and admit that the development of these entozoares is found connected with a diminished activity of the normal nutrition of the liver. (Précis d'Anatomie Pathologique, tom. ii.)

Observations are still wanting to establish the exact relative frequency of suppuration as the result of hepatitis in its acute and chronic stage; there can be little doubt, however, that this lesion is much more frequently the result of an acute than of a chronic inflammation.

With respect to the frequency of peritoneal adhesions it may be stated that these, which we have seen to be by no means constant in the acute disease, are commonly met in chronic hepatitis. In this disease the convex surface of the liver is generally found adherent to the parietal peritoneum by strong and organized adhesions. On its concave surface we may also meet adhesions with several portions of the abdominal viscera, though, as far as we have seen, these are not so frequent nor so general as those of the convex portion.

Symptoms of Hepatitis.—Inflammation of the liver has long been described as occurring under two forms, the *acute* and *chronic;* but although numerous cases will be met with where it would be difficult to declare to which of these species the disease belongs, yet in a practical point of view the division is convenient. Let us examine the symptoms, progress, and termination of the first or acute species.

Acute Hepatitis.—In the different elementary works on the practice of physic, the symptoms of this disease are described as occurring in a manner much more constant than the state of the science can permit us to believe, and in this way the student is misled, and gets a very false and contracted view of the affection. In fact, there is no one symptom mentioned that may not occasionally be absent; and, on the other hand, all may arise from other causes besides hepatitis. The symptoms may be considered as local and general; the *local* being, principally, pain, tenderness, and tumefaction; the *general*, fever, and lesion of the digestive and in some instances of the nervous and respiratory systems. Of these, the first two, namely, fever and lesion of the digestive function, are by far the most frequent, a circumstance to be expected when we recollect the general complication of hepatitis with gastro-intestinal disease. (See Gastro-Enteritis.)

Acute hepatitis may be generally described as commencing with that group of symptoms indicative of inflammation in the digestive system; in other words, the patient at first appears to be attacked with gastric or bilious fever, to which succeed, sooner or later, symptoms of the hepatic disease. There is often then high fever, the type being generally more inflammatory and less typhoid than that which results from a simple gastro-enteritis. The pulse is more frequently strong and full; there is thirst, a furred and yellowish tongue, and frequently vomiting, sometimes of a bilious, at other times of a dark-coloured matter. The bowels are commonly irregular or costive, and the discharges present a great variety of appearances according as the biliary secretion is more or less affected, and also according to the degree of complication with gastro-intestinal disease. The urinary secretion is also affected, being almost always scanty and very high coloured.

In addition to these symptoms we have the local indications of hepatitis, which are, principally, pain, tenderness, and tumefaction. The pain is felt in various situations, and occurs with various degrees of intensity. In some cases the patients describe it as a stitch in the side, aggravated by respiration or motion; in others the pain occurs about the cartilages of the lower ribs, or it may be felt in the lumbar region. Much has been written about the occurrence of pain in the right shoulder in cases of hepatitis; from our experience we would say that this is an extremely rare symptom, and one by no means pathognomonic of the disease, an opinion borne out also by the experience of Dr. Mackintosh (Elements of Pathology and Practice of Physic, vol. i.) in these countries, and of Andral in France. (Clinique Médicale, Maladies de l'Abdomen.) There can be no doubt that practitioners are often misled from attaching an unmerited degree of importance to the presence or absence of this symptom. Generally speaking, the pain is more acute when the inflammation is superficial,—a circumstance illustrative of the general law, that in parenchymatous inflammations the pain is more severe when the disease approaches or involves the surface of the organ.

The symptom which we regard as next in importance to the pain is the tumefied and tender condition of the organ. When the belly is flaccid and the intestines are empty, there is seldom much difficulty in detecting the hepatic enlargement. We then generally observe the right hypochondrium and the epigastric region full, and the edge of the liver can be felt descending more or less below the costal cartilages. Sometimes the ribs appear tilted out, but the intercostal spaces preserve their relative positions with respect to them; a point of great importance in the diagnosis between hepatic and pulmonary diseases. But where the belly is distended by either fæcal matter or air, it becomes extremely difficult to ascertain the enlargement of the liver. In such a case we would always recommend that a dose of opening medicine should be given, followed after some time by a purgative injection, after the operation of which the examination of the hepatic region will

be greatly facilitated. We shall also derive important information by the use of mediate percussion by means of the pleximeter, as recommended by M. Piorry, from whose recent work we shall quote.

"In some acute cases of hepatitis, or rather in sanguineous congestions of the liver, it has been easy to demonstrate, at the Salpêtrière, the Pitié, and at the Hôtel Dieu, that the liver is susceptible of great increase of volume, and that the dimensions of this gland diminish rapidly after a copious bleeding, and sometimes also by strict regimen, which by itself produces a loss of blood. The diminution of the hepatic organ varies from one to three inches, from above downwards, in the twenty-four hours; this is still greater in proportion as the blood drawn is more considerable. Not only has this fact been observed with old men in whom the venous circulation, embarrassed by disease of the heart, and particularly its weakness, explains the tumefaction of the liver, but also in adults, in cases of plethora and acute fevers. I could easily accumulate twenty observations to support this proposition. M. Vidal, one of the house pupils connected with my attendance, has just related to me three most remarkable facts taken most carefully. I shall confine myself to the following: A young man discharges a loaded pistol direct against the region of the liver; the ball, however, does not penetrate, which singular fact may be attributed to the presence of air between the muzzle of the piece and the ball, the pistol being applied to his clothes so firmly as to stop up the muzzle: his clothes are, however, torn, and the foreign body, after having violently contused the skin, falls at the feet of the wounded man. The first few days no accident of importance occurred; the circumference of the liver was bounded by a black line. The fourth day there was fever, flushed face, and dyspnœa very intense: this was referred to the liver; this organ above and below exceeded by an inch or more the former line of demarcation. A copious bleeding was tried; the next day the liver had resumed its former dimensions, and the severe symptoms disappeared. The cure was rapid. (*Piorry*, du Procédé Opératoire, etc. Paris, 1831.)

In using the pleximeter we should employ it over the epigastrium and hypochondrium, and also over the lower portion of the chest both anteriorly, laterally, and posteriorly. By this means, the extent of the hepatic tumefaction can be generally determined with ease. In some instances the tumefaction is more evident in the superior, in others in the inferior portions of the liver; when, however, the belly is much distended, this mode of observation is liable to many difficulties: thus, when the intestines contain much solid and fluid matter, we cannot estimate the extent of dulness inferiorly; and on the other hand, when they are distended by flatus, the liver is pushed upwards, under which circumstances the dulness of the lower part of the chest ceases to be a measure of the hepatic tumefaction.

Jaundice has been described as an attendant on hepatitis, but it is not a constant symptom. The patients have generally a slightly yellowish tinge, particularly in the face, similar to what is observed in gastric or bilious fevers, but very different from true icterus. In none of the cases observed by us at the Meath Hospital was there jaundice; and Andral relates numerous cases of hepatitis where this symptom was absent: it may, however, occur in acute hepatitis; but facts are still wanting to explain its absence in some cases, and its presence in others. Of one fact we are certain, that jaundice, when induced by inflammation, is much more frequently the result of a duodenitis than of an inflammation of the liver. From the known effect of a duodenitis, simple or complicated with gastric inflammation, in the production of icterus, (*Marsh*, on Jaundice, Dublin Hospital Reports. *Broussais*, Commentaries, &c.) it becomes an interesting question to determine how far the complication of gastro-intestinal inflammation in hepatitis may act in producing the symptom of jaundice. The following table of cases, taken from the writings of Andral, Louis, and from the report of the Meath Hospital, may assist in throwing some light on the subject. The first column states the condition of the liver, the second that of the gastro-intestinal apparatus and ducts, and the third that of the skin.

State of the liver.	*Digestive tubes and ducts.*	*Skin.*
Acute hepatitis	Healthy; ducts free	Jaundice.
Red softening	Healthy; ducts free	Jaundice (slight).
Red induration	Ditto ditto	Jaundice.
Numerous abscesses	Ditto ditto	Jaundice.
Abscess	Ditto ditto	Jaundice.
Ditto	Ditto calculus	Jaundice.
Ditto	Ditto healthy	Jaundice (slight).
Hepatitis with tumefaction	Chronic gastritis	Jaundice.
Hypertrophy	Chronic gastro-duodenitis; ducts free	Jaundice.
Vast abscess	Gastro-enteritis; ducts healthy.	Jaundice.
Numerous small abscesses	Slight enteritis; ducts free	Jaundice (slight).
Ditto ditto	Gastritis; gall-bladder atrophied; calculus in cystic duct	Jaundice (deep).
Numerous abscesses	Colitis; ulcerations of gall-bladder	Jaundice.
Hypertrophy	Chronic gastro-duodenitis	No jaundice.
Numerous abscesses	Chronic gastro-enteritis; duodenum healthy	No jaundice.
Ditto ditto	Gastritis	No jaundice.
Vast abscess	Ditto	No jaundice.

State of the liver.	*Digestive tubes and ducts.*	*Skin.*
Abscess and gangrene.....	.....	No jaundice.
Abscess	Duodenitis	No jaundice.
Chronic abscess in right	Chronic gastro-duodenitis	No jaundice, (slight yellowness at the commencement.)
Acute ditto in left lobe		
Vast hepatic abscess	Healthy	No jaundice.
Numerous abscesses	Colitis	No jaundice.
Red softening	Gastro-enteritis.....	No jaundice.

It is obvious, from the inspection of this table, that we cannot arrive at any explanation of the presence or absence of jaundice in cases of hepatic inflammation, from the consideration of the circumstance of gastro-intestinal complication. We see here cases of hepatitis with jaundice, in which the digestive tube was free from disease, and the same symptom with gastro-intestinal inflammation; and, in the cases of hepatitis without jaundice, the tube was healthy in some and diseased in others.

We may remark, while on this subject, that in hepatitis the biliary secretion is variously affected. In some it appears to be suspended, while in others, even after extensive suppuration of the liver, the gall-bladder has been found filled with healthy bile. We have observed these facts repeatedly in the Meath Hospital. Thus, in a case where a great number of abscesses were formed, the gall-bladder contained a perfectly transparent viscid fluid which did not coagulate by heat or the addition of nitric acid; the fluid was perfectly colourless, and in short presented all the characters of pure mucus. Notwithstanding this appearance of the contents of the gall-bladder, it is most remarkable that the intestines contained a quantity of yellow mucous and fæcal matter. In this case the mucous membrane presented indications of inflammation.

In two other cases, where the most extensive destruction of the liver had taken place, the gall-bladder was found to contain a bile healthy to all appearance. In the first of these a chronic abscess existed in the right, and a recent abscess in the left lobe. In the second, the organ was completely burrowed by numerous abscesses. In the different cases of hepatic abscess recorded by Louis, the greatest variety in the contents of the gall-bladder occurred. From these facts we seem justified in concluding that in acute hepatitis, and probably also in the chronic disease, we cannot form any exact diagnosis of the state of the liver from the appearance of the biliary secretions in the stools, inasmuch as in one case it is altered in its quality in a variety of ways, while in another, apparently the same condition of the organ, no perceptible change is observable. The truth is, that neither its presence, absence, nor alterations, give us any data to enable us to conclude as to the stage, extent, progress, or termination of the inflammation; and it is plain that under these circumstances the state of the stools will but little assist our prognosis. It is probable, however, that a very copious secretion of bile is more favourable than the contrary, as the inflammation of secerning organs is generally more inveterate when their secretion is arrested.

When hepatitis is once formed, it may terminate by resolution or by suppuration; or the irritation may continue in a modified manner, so as to be classed among chronic diseases of the liver. The indications of resolution are, in the first instance, the subsidence of the fever, the gastric symptoms, and the pain: this is followed by the disappearance of the tumefaction, which, though generally the last in the order of symptoms, often occurs with great rapidity. The infra-mammary and postero-inferior portions of the chest recover their clearness of sound on percussion; the dilatation of the side is no longer observed; the right hypochondrium and epigastric region lose the tension and fulness which occurred during the acuity of the disease. Although a few cases of suppuration without perceptible tumefaction of the organ have been met with, yet from our own experience we would say that the subsidence of the swelling is one of the most certain indications of the resolution of the disease, certainly more so than the disappearance of the fever and pain.

But when suppuration is to occur, we often find that the tumefaction, so far from diminishing, becomes increased, and this at a time when the fever is frequently changed in character and assumes a hectic type. Shiverings, more or less severe, are observed, with or without perspirations; the pulse becomes small and rapid; the countenance is pale, and a sour smell of the surface is perceptible. In one case we have observed a miliary eruption. There is generally a constant sense of weight and uneasiness in the right hypochondrium, and the pain has in some instances been found as it were to concentrate itself on a particular spot, probably corresponding to the principal collection of pus. After some time a fluctuating tumour may appear generally in the epigastrium or some part of the right hypochondrium, which is followed by discoloration of the integuments; but in other cases no such occurrence takes place, and we must be guided by the history of the case and the constitutional symptoms in forming the diagnosis of suppuration. Should the tumefaction persist, with a fever either of the continued or remittent type, we may suspect the formation of matter. When, however, the abscess forms so as to be perceptible by manual examination, we may observe the following conditions:—1, a generally enlarged state of the organ, in which, though no perceptible fluctuation exists, a doughy or boggy feel is communicated over a greater or less portion of the tumour; 2, distinct tumefaction below the margin of the rib; 3, a tumour in the epigastrium; and, 4, a bulging of the false ribs, with more than usual fulness of the intercostal spaces.

But it must be always borne in mind, that although the constitutional symptoms frequently undergo a remarkable change at the moment of suppuration, yet there are abundance of cases in which the change is scarcely if at all perceptible. To this we shall recur in speaking of the difficulties in the diagnosis of this disease.

The constitutional symptoms which are of

most value are, the supervention of night perspirations, shiverings, cold sweats, clamminess of the skin, and frequent fainting sensations. If this state has arisen in a case where it has been found impossible to affect the system with mercury, the diagnosis of abscess may be made with a great degree of certainty. In this last and most important statement, the best East India practitioners agree, and we have heard one gentleman, who occupies a high rank in the service, declare that he never yet knew a case of abscess of the liver in which ptyalism was induced, even although the largest quantities of mercury had been exhibited. Mr. Annesley says, "that there can be no doubt that the system will not be brought under the full operation of mercury, or that ptyalism will not follow on the most energetic employment of this substance, when abscess exists, although a slight tenderness of the gums will be produced by it." As far as our experience in the Meath Hospital has gone, we should say that the same circumstance holds good in the case of hepatic suppuration in these countries; but it is not peculiar to inflammation of the liver, as it is observed in other cases of intense visceral inflammation, in which, when ptyalism is induced, it is obviously the effect and not the cause of the reduction of the visceral disease; and we have no doubt that, from not properly estimating this circumstance, practitioners have erred with respect to the curative powers of mercury, and have done injury by the introduction of enormous quantities of this mineral into the system at a time when the violence of the local action prevents its specific and sanative effects on the economy.

The terminations of these cases of hepatic abscess are various. We have already alluded to the internal openings of the abscess in describing the pathological anatomy of the liver in a state of inflammation. In these cases the diagnosis is to be made on the same principles which Louis has laid down in speaking of peritonitis from perforation of the intestine: there is a sudden appearance of a new train of symptoms, accompanied in almost all cases by subsidence of the hepatic tumour. Thus, when the matter makes its way into the lungs by the mechanism which we have before described, a sudden and copious expectoration of puriform matter has been commonly observed: this is accompanied by a remarkable diminution in the hepatic tumour. Should these symptoms arise in a case where previously there had been no evidence of disease in the pulmonary parenchyma, the diagnosis may be still more certain. We had once an opportunity of making a stethoscopic observation of this most interesting lesion; the patient had recovered from an attack of that violent gastric fever accompanied by yellowness of the skin which we have described in the article Enteritis, when he again came under our care, labouring under symptoms of hectic fever, which proved ultimately to proceed from hepatic suppuration. This patient had a constant dry cough, which led us to make repeated stethoscopic examinations without our being able to detect any disease whatsoever in either lung: in less than twelve hours after the last stethoscopic observation the patient was suddenly seized with a feeling of suffocation, and began to expectorate large quantities of perfectly formed pus, of which in the course of the night he discharged upwards of a pint and a half. On the following morning the left lung, which the day previously had presented no morbid sign whatever either by the stethoscope or percussion, was found completely dull over the whole region of the lower lobe, with complete extinction of the respiratory murmur: there was no bronchial respiration, no resonance of the voice, dilatation of the side, nor displacement of the heart; nor was there any constitutional symptom indicative of either pleuritic or pneumonic inflammation. The patient continued to expectorate copiously for some days, and after the second day the morbid phenomena of the chest began to subside. We had, first, a mucous rattle audible at the root of the lung, which gradually extended over the dull portion, and was followed by a return of the respiratory murmur and resonance of the voice.

This stethoscopic observation, for the accuracy of which we pledge ourselves, is explicable only by the sudden filling of all the bronchial tubes with purulent matter. Let us observe, first, the sudden supervention of dulness and absence of respiration in a patient whose chest a few hours before presented no morbid phenomenon; this is accompanied by a copious expectoration of purulent matter, and there are no constitutional symptoms of pleurisy or of pneumonia. The absence of these symptoms is of great importance, because if the disease had proceeded from either of these lesions, it must have been of extraordinary violence, and would have certainly been accompanied by high constitutional and local symptoms. There was no dilatation of the side, or displacement of the heart, so that the diagnosis lay between hepatization of the lung and the sudden filling of the tubes with pus; but there was no bronchial respiration nor resonance of the voice, which would have occurred had it been hepatization, but which were absent because the large tubes were completely filled; and further, during the recovery of the patient the phenomena of the voice were exactly the reverse of those in pneumonic resolution. Thus, in the latter the resonance *decreases*, while in this case it *increased*;—in hepatization, because the air-cells recover their permeability, and the morbid subsides into the natural bronchophony;—in the case under consideration, because the emptying of the tubes permitted the return of the natural resonance of the voice. The resolution of pneumonia is accompanied by *decrease* of bronchophony, while in the case before us it was accompanied by *increase*.

In the majority of cases the matter discharged from the chest consists of well-formed pus. In a case, however, reported by Annesley, the opening of an hepatic abscess was followed by a violent purulent and bloody expectoration; the patient experienced a great sense of suffocation when he lay on his back, and on dissection a vast hepatic abscess was found communicating with the posterior portion of the lung. We have witnessed a case of the same lesion, in which, whenever the patient turned on the left side, a large quantity of purulent matter was discharged from the trachea.

It is hardly possible to confound this accident

with any disease of the lung, properly so called, particularly if by stethoscopic observation we have been satisfied of the previously healthy condition of the organ. The only cases which might possibly be confounded with it are the rare instances of the opening of an empyema into the lung, or the sudden secretion of purulent matter in quantity by the bronchial mucous membrane, of which a few instances are recorded.*

We have already spoken of the rarity of hepatic abscess opening into the general cavity of the pleura—a circumstance explicable by the adhesions which are formed between the two surfaces of the pleura, and which have the effect of directing the matter into the substance of the lung. From the rarity of these cases, it is difficult to state the symptoms of this lesion; yet in a case where a sudden occurrence of the signs of effusion into the pleura, accompanied by the disappearance of those of the hepatic abscess, were observed, the diagnosis might be made with a great degree of probability.

A not unfrequent termination of hepatic abscess is by the establishment of a communication with some portion of the digestive canal. The stomach, duodenum, and colon, are the parts in which the communication has been most commonly observed; and the circumstances which appear to influence the point of communication are principally the situation of the abscess and the general volume of the hepatic tumour. When the matter makes its way into the stomach, a sudden vomiting of purulent fluid, with subsidence of hepatic tumour, has been observed. When, on the other hand, it opens into the intestine, we have a sudden diarrhœa, followed by the same phenomenon. From instances of recovery under these circumstances, it seems fair to infer that a cure by cicatrization of the opening is not unfrequent; but the opening may become fistulous, and continue until the fatal termination of the case. This occurred remarkably in a case the particulars of which we shall just now detail, and which we before alluded to.

Rupture into the peritoneal sac seems to be more frequent than the opening into the pleura, a circumstance to be expected from the smaller degree of liability of this membrane to form adhesions. When it does occur, we have violent peritonitis supervening; but the full evacuation of the abscess is not a necessary consequence. The following unique case is highly instructive, as illustrating the rupture of hepatic abscesses both into the digestive canal and peritoneum.

A man, aged 39, was admitted into the Meath Hospital in August, 1828, labouring under hectic fever, with cough and nausea. He complained of great soreness from the fourth rib on the right side downwards. The hypochondrium was full and tender, and the side dilated one inch and a half, without distension of the intercostal spaces. Having recognised that the disease was hepatic, and suspecting that an abscess, deep-seated, had formed, we determined on performing the operation, first proposed by Dr. Graves, of dividing the abdominal parietes as far as the peritoneum, and keeping the wound plugged with lint. This was done, yet after six days had elapsed, no matter made its appearance. Soon after this a circumscribed tumour, evidently containing fluid, suddenly appeared between the median line of the epigastrium and the termination of the wound. It is important to remark that this tumour was not preceded by any local induration, but at once presented fluctuation. In consultation, however, it was determined to open it cautiously by means of a lancet, when, in place of matter, there was a gush of dark-coloured bile: the tumour disappeared, but fulness of the side continued. About four hours after this operation the patient expressed a sudden desire to go to stool, and passed two copious discharges of purulent matter with bilious fæces. This was followed by remarkable improvement, and the tumefaction rapidly diminished, so that in a few days all swelling of the right hypochondrium had disappeared. A diarrhœa, however, continued from the time of the disappearance of the tumour, and resisted every attempt to check it. Twenty-three days after the subsidence of the first tumour, a small hard swelling was observed in the epigastric region, about the size of an egg; this increased daily, and soon became fluctuating. On the thirteenth day after this, sudden and violent peritonitis set in, with subsidence of the epigastric tumour. He lived eight days longer, the diarrhœa continuing until his death.

From considering the various symptoms in this case, we made the following diagnosis publicly, before dissection; viz. 1. that the gall-bladder would be found to have been punctured, but that from peritonitis not having set in on that occasion, it was probable that its fundus was adherent; 2. that a chronic abscess would be found in the right lobe of the liver, which was the cause of the first symptoms, and in all probability of the persistent diarrhœa, from a communication remaining open between it and some portion of the digestive tube; 3. that a recent abscess would be found in the left lobe, which had opened into the peritoneum, and had caused death by peritonitis.

On dissection, the peritoneum was found of a deep-red colour, containing a quantity of serous fluid, in which was a large quantity of flocculi, forming masses having the consistence of jelly; the liver was generally adherent to the diaphragm and abdominal parietes, the adhesions of the right lobe being strong and ancient, those of the left soft and recent. In the left lobe an abscess of the size of an orange was discovered a little above its lower edge, and communicating with the peritoneal cavity by a fistulous opening, sufficiently large to admit a quill. In the right lobe we found a cavity of the size of an egg, empty, and lined with a semi-cartilaginous membrane of a dark iron-grey colour: this communicated with the duodenum by an opening large enough to admit the finger with ease. The gall-bladder presented superiorly a spot exactly corresponding to the size and form of a lancet puncture, which was covered by a thin transparent membrane. (Dublin Hospital Reports, vol. v.)

But hepatic abscess frequently proves fatal without any rupture internally or externally. In

* See *Van Swieten*, Comment. vol. iv. p. 60. Les Ephemerides des curieux de la Nature. *Baumes*, Traité de la Phthisie. *Hippocrat.* de morbus vulgaribus. *Andral*, Clinique Médicale.

these cases, as Broussais has well observed, the diseased action is seldom confined to the liver, but commonly occurs in some other organ, such as the gastro-intestinal mucous membrane, the lungs, or brain; of these the first is by far the most frequent. The actual state of pathology, however, does not permit us to adopt the opinion of Broussais as to the constancy of this complication, but the fact of its frequency is well established, and becomes of great importance in practical medicine. In all the cases of abscess of the liver recorded by Andral, there is but a single instance where the disease occurred without complication with lesion of other organs.

Suppuration of the liver has occurred without any of the characteristic symptoms of hepatitis. Thus, in the twenty-sixth observation of Andral, numerous abscesses, with redness and softening of the hepatic tissue around them, were found, yet the patient never had pain or tumour in the region of the liver, nor was he jaundiced: in this case there was complication with acute pneumonia and gastritis. In another case, where a scirrhous state of the stomach existed, numerous partial inflammations of the liver and an abscess were discovered; the patient never had either icterus or pain either in the hypochondrium or right side of the chest. The same author details a case where an hepatic abscess with gangrene was discovered after death, and in which all the characteristics of an hepatic affection were absent. The patient laboured under a chronic bronchitis and gastritis. We have known two cases where numerous abscesses were found in the liver, and in which the symptoms were merely those of continued fever, without any indication which could lead to the suspicion of the disease. Other instances might be quoted, but such cases are comparatively rare, and should not discourage the student, or render him too sceptical as to the powers of diagnosis.

In certain cases, the gall-bladder becomes distended with bile so as to form a tumour in various situations along the margin of the liver, representing in many particulars the phenomena of an hepatic abscess so completely, that the most eminent practitioners have been deceived in their diagnosis. It is extremely difficult to lay down rules by which this affection can be distinguished with absolute certainty. The obstruction of the ducts in most cases has been preceded by more or less of indications of hepatic disturbance, which it is impossible to say did not proceed from disease of the parenchyma of the liver. In the case which we have recorded, there was actually an hepatic abscess at the time when the distension of the gall-bladder occurred, and which was evidently its cause, so that in this case we had the local and constitutional symptoms of hepatic suppuration preceding the tumour, caused by the gall-bladder. In this case, then, the previous symptoms could only mislead us as to the nature of the tumour. We are not, however, aware of any other case where the tumefaction of the gall-bladder was preceded by an hepatic abscess.

In the first volume of the Dublin Hospital Reports, a most interesting case of enlargement of the biliary duct is recorded by Mr. Todd. The patient, a delicate girl, had been in bad health for some months previous to her death, during which she had had severe fever, with several relapses. When she was first seen by Mr. Todd, she was nearly insensible; she moaned incessantly, and frequently screamed, as if seized suddenly with acute pain; the skin was of a deep orange colour, and she was greatly emaciated. On examination, it was found that the abdomen was distended with fluid, and that the epigrastic and right hypochondriac regions were occupied by a tense swelling, which could be traced extending even below the umbilicus. A distinct fluctuation was perceptible at the most prominent point, a little below the ensiform cartilage, and a little to the right of the linea alba. This part was extremely sensible, and hence it was thought probable that a large abscess of the liver was here approaching the surface. With this impression, and anxious to afford immediate relief, Mr. Todd made an opening into the most prominent part of the tumour, when a thin fluid coloured with green bile escaped; a canula was then introduced with a view to prevent the escape of the fluid into the peritoneal cavity, when upwards of two quarts of a viscid green bile were discharged. After the operation, all the tumefaction of the abdomen had subsided, and no enlargement of the liver nor any other swelling could be detected. In the evening, however, the belly became swollen, painful, and tense, and the patient died on the following day. On dissection, the peritoneum was found inflamed, and containing a serous and bilious fluid: the liver was perfectly healthy, and the gall-bladder was found empty and contracted; but the hepatic and common ducts were found to be enormously distended, forming a sac, which still contained more than a quart of bile, and extending from the porta of the liver to the os sacrum, lying behind the duodenum, pancreas, and root of the mesentery, and stretching in a transverse direction, so as to cover the anterior surface of the right kidney, and the greater part of the left.

Andral relates several cases of distended gall-bladder forming an evident and fluctuating tumour in various portions of the abdomen. He has seen it, 1st, immediately below the cartilaginous portions of the right ribs; 2dly, lower down in the hypochondrium; 3dly, in the iliac fossa; and, 4thly, in the epigastric region. In a case of aneurism of the hepatic artery, which we have lately observed, the gall-bladder formed a fluctuating tumour very near to the right ileum, and the biliary ducts were found in a similar state to that described by Mr. Todd, only distended to a less degree. We believe that in all the cases, with the exception of that which we have recorded, there was jaundice; and it is probable that if the gall-bladder had not been punctured, and that the abscess had continued to press on the ducts, this condition would ultimately have been induced. In this case, also, it is very important to compare the appearance of the two tumours with a view to their diagnosis. That of the gall-bladder appeared suddenly, without being preceded by local pain or induration, but was at once fluctuating; that arising from the abscess of the left lobe was preceded by pain and induration; and fluctuation

did not appear until some days after its occurrence. This observation may be of utility in determining the point in future cases.

Chronic Hepatitis.—A great number of affections of the liver have been classed under this general term; such as induration, scirrhus, tubercle, hypertrophy, atrophy, &c., &c. In fact, we cannot say with certainty what the condition of the liver will be on dissection in a case where symptoms of chronic irritation have existed. We may, indeed, recognise an enlargement or an induration, but it appears rash to go farther than this. The liver, like other organs, however, being subject to chronic inflammation, we may recognise this condition, although we cannot say what particular alteration it may have induced.

The disease may set in with attack of acute hepatitis, or may from the commencement preserve a slow insidious character. In some cases there is more or less of fever, while in others the patient is apyrexic. The principal phenomena are various derangements of the digestive function, and it is often next to impossible to pronounce on the actual condition of the gastro-intestinal mucous membrane. In fact, chronic disease of the liver and of this surface are commonly combined. If, in addition to pain long continued in the region of the liver, increased by excitement, and accompanied by tenderness and tumour, we observe a sallow countenance, a dry skin, foul tongue, scanty and high-coloured urine, with occasional attacks of jaundice, we may safely make the diagnosis of chronic hepatitis.

In the less acute forms of the disease the local symptoms of an hepatic affection are often very indistinct, and the case presents many of the usual phenomena of a chronic gastro-enteritis. In addition to these, the pain about the right shoulder, when it does occur, the distension and oppression in the epigastrium and right hypochondrium, the bitter taste in the mouth, the sallow appearance of the countenance, the elevation of the shoulders, and the wasted state of the body, are the circumstances which in warm climates are relied on as indicative of hepatic disease.

It is stated that, when the surfaces of the liver are the seat of disease, the pain is more decided, and that, as the superior or inferior surface is chiefly affected, so in the first case the symptoms will be referred to the chest, and in the second to the stomach and bowels. An eminent writer says, that when the superior and exterior part of the right lobe is the seat of disease, the patient reclines with most ease on the right side, a dragging sensation being felt on turning to the left. From this sensation it is supposed that we may infer the existence of adhesions between the lobe of the liver and the right side.

Nothing can be more various than the terminations of this disease which have been observed. In fact, every one of the known organic changes of the liver has been found in cases where the patient laboured under symptoms of chronic hepatitis. Most of these certainly may be looked on as the results of the inflammatory action, the modifications in their nature being probably connected with the constitutional dispositions of the patient. In fatal cases, death is induced by various circumstances. In some cases an acute hepatitis supervenes upon the chronic, but in the majority the patient is cut off in consequence of disease of other organs. He may be attacked by peritonitis, either in consequence of the rupture of an abscess or of the gradual extension of disease to the serous surface: he may be attacked with enteritis or dysentery, which is a common termination in warm climates: pulmonary or cerebral disease may set in; and dropsy, with or without an affection of the heart, is not unfrequent.

The diseases with which chronic hepatitis has been confounded are principally the following: chronic gastro-duodenitis, scirrhus of the stomach, chronic pleurisy of the right side with empyema, and a neuralgic affection, of which the seat appears to be in the hepatic plexus.

In the articles Enteritis and Gastro-Enteritis we have alluded to the great frequency of the error of confounding the affection of the gastro-intestinal mucous membrane with that of the liver, and have dwelt on the injurious consequences of this mistake. With respect to the diagnosis between this disease and chronic pleurisy with effusion, we would say that there is hardly a case where the tact of the practitioner is more requisite than in this. We will suppose that he is called to see the case for the first time after considerable enlargement of the organ has occurred. He will often find that the history of the case gives him but little assistance, as the two affections are often accompanied by very similar symptoms; neither will he derive decided assistance from the stethoscope and percussion. In both cases we may have extensive dulness of the side, absence of respiration, resonance of the voice, or bronchial respiration. The side will be dilated in both, and the decubitus generally on the affected side. Neither will the existence of a tumour in the abdomen be unequivocal, as in the one case it may occur from hypertrophy of the organ, in the other from displacement.

From our experience we should say that the indication which is the most unequivocal is drawn from the state of the intercostal spaces. When the side is dilated by a fluid, as in empyema, the spaces are raised either to a level with the ribs or even protruded beyond them, and the side has generally a smooth and rounded appearance. On the other hand, when the dilatation is produced by a solid tumour, such as an enlarged liver, the reverse of this occurs; the pressure being exercised on the ribs, these are pushed outwards, but the intercostal spaces preserve their relative positions with them, and the side does not present any thing of the smooth and rounded appearance which we have described. (See Dub. Hosp. Rep. vol. v.) There are certain cases, however, where even this diagnosis is not applicable, such as where the patient is fat, the integuments œdematous, or the belly distended by fluid. Under such circumstances the difficulty of diagnosis is extreme.

It appears to us that the attention of British practitioners has not been sufficiently called to the frequency of the neuralgic affection of the liver which is commonly seen in hysterical subjects, and has been noticed by Andral in his Clinique Médicale. "We sometimes observe in the region of the liver severe pain, which cannot be accounted for after death by any lesion of the viscus or its

excretory ducts. These are cases of hepatalgia or hepatic colic. The circumstance just mentioned, and, moreover, the nature of the pains, their intermission, and the state of good health which often exists in the intervals,—all lead us to believe that these pains have their site in the numerous nervous filaments which are distributed in the liver, and which are derived either from the pneumogastric or the great sympathetic." (Maladies de l'Abdomen, t. ii. p. 26.)

The persons in whom we have witnessed this affection were females. In some of these a decidedly hysterical tendency existed, while in others this disposition was scarcely if at all indicated. In one case the condition of the spine lately denominated "spinal irritation" was present. The principal symptom in these cases was a constant pain in the region of the liver, which lasted for years, and was subject to occasional and violent exacerbations from various causes, such as mental emotion, fatigue, over-excitement, derangement of the bowels, or the occurrence of menstruation. During the exacerbation the pain is excruciating, —to all appearance more violent than that in the most intense inflammation,—and is generally accompanied with exquisite tenderness of the right hypochondrium. It has been stated to have been sometimes accompanied by a slight jaundice; but of this we never witnessed an instance, as, in the cases which we have observed, none of the usual symptoms of hepatic irritation, with the exception of the pain, existed. There was never fever, nor tumefaction, nor a bilious state of the urine, foulness of the tongue, thirst; nor were the alvine evacuations apparently affected, although the disease had been present for months or even years. Further intervals occurred during which the patient enjoyed a respite from pain, and presented no local nor general symptom of hepatic derangement. The diagnosis of this disease is then to be drawn from the violence of the pain, which is greater than that of inflammation, combined with the absence of fever, tumour, and the other indications of structural disease of the liver. We may also remark, that in several cases which have occurred under our observation the patients were subject to neuralgic affections in other situations, as the face or extremities: in one, severe dysmenorrhœa had long existed.

It is now some years since we were consulted in the case of a lady of luxurious habits and highly nervous temperament, who, while in India, had been attacked with pain in the region of the liver, which was supposed to arise from acute hepatitis. For this she was largely bled, both generally and locally, and brought under the influence of mercury, without relief. She was ordered to return to England, and on the passage was several times bled and twice mercurialized with the same intention. Some time after her arrival in this country, the pain became again severe, and occurred with violent exacerbations. Each attack had been treated as if it had been one of acute hepatitis, she having been repeatedly bled, leeched, blistered, and mercurialized. Temporary relief used to be afforded by the bleeding, but the disease constantly recurred; her constitution had become shattered, and she was constantly subject to the most violent hysterical paroxysms: the stomach had become so irritable that every thing was rejected, and the patient's sufferings were indescribable. Such was the condition of this lady when we were first called to see her; it was plain that the disease had resisted the most rigorous and long-continued antiphlogistic treatment. We found that there never had been any fever, that the right hypochondrium was perfectly supple, the lower part of the chest sounding clear, the tongue clean, the eyes and complexion clear, and the patient subject to neuralgic affections in other parts of the system. Under these circumstances, we determined on treating the affection as a neuralgia. Further bleedings were inhibited, contrary to the wish of the patient, who, as before stated, experienced temporary relief from them. She was put on a generous diet, sent to the country, and directed to use free doses of the carbonate of iron. This treatment proved perfectly successful, and in the course of a few weeks the lady was in the enjoyment of a state of health and comfort to which she had been a stranger for more than two years previously. We know of another case of a lady who had been actively treated for supposed hepatitis in the country without success. She was advised to come up to town to place herself under the care of physicians, for the purpose of undergoing a course of mercury. On examination, her medical attendant could find no evidence of hepatic disease except the pain. She was also treated by the carbonate of iron with complete success. Since then we have known several cases where the error of confounding this affection with inflammation has been committed, — an error always full of danger, but in Great Britain peculiarly unfortunate, from the empirical and almost universal employment of mercury in all hepatic affections. We have at this moment under our care a most deplorable example of the effects of this error, where the most profound lesions of the nervous system have been induced by the long-continued use of mercury.

Causes of Hepatitis. — The exciting causes of hepatitis may be enumerated as follows: residence in a tropical climate, intermittent or continued fever, gastro-intestinal inflammation, suppression of habitual fluxes, abuse of spirituous liquors, injuries of the side, wounds of the head, congestion from venous obstruction, suppression of cutaneous eruptions, exposure to cold, gallstones, &c.

Treatment. — When a patient has been attacked with symptoms of acute hepatitis, the disease being still in its early stages, and no evidence of suppuration present, the treatment should be commenced by a free bleeding from the arm, which, if the subject be robust, and the inflammatory fever high, should be pushed so as to produce some effect on the circulation. It would be always well to see the patient again in the course of from four to six hours, when, if the pain and oppression should have returned, and the inflammatory fever again be lighted up, the bleeding should be repeated without hesitation; a less quantity of blood, however, will generally answer the expected purpose. The bowels should be opened by a free dose of calomel, followed by saline medicine, and assisted by a purgative injection. The patient will thus be brought into the state best adapted

for deriving advantage from local bleeding; and we would impress strongly on the mind of the practitioner, that, although the exhibition of mercury is sometimes indispensable, he must place his chief reliance on general and local bleeding, both as the surest means of arresting the disease, and of ensuring the beneficial action of mercury should its exhibition become necessary. In warm climates it has been observed that in some cases the operation of bleeding is followed by faintness before a sufficient quantity is taken, and the blood is dark and grumous. In this case, as has been observed in other violent inflammations, (see *Rush* on the Yellow Fever,) the bleeding is soon followed by more violent excitement of the circulation, when a second bleeding is indicated, and the patient will bear the loss of a much greater quantity of blood; and this will then be found to present the buffy appearance in a much higher degree. The second bleeding also gives much greater relief to the patient.

From our experience we would say that general bleeding has not the same marked influence over hepatitis that it has over peripneumony, but appears principally useful in preparing the patient for local depletion, which seems to have the most direct influence on the disease. We have seen a case where upwards of a hundred ounces of blood were drawn at different times, and in which no apparent effect was produced on the inflammation until local bleeding was performed. In a robust adult not less than thirty leeches should be applied after the general bleeding, to the most painful part of the side, a measure which will be followed by still greater advantage if the bowels have been previously opened; and to ensure this result, purgative injections should be used to assist the action of the medicine administered by the mouth. When the patient can bear it, the greatest advantage will be derived from the application of a cupping-glass, fitted with an exhausting syringe over the leech-bites, by which means a much greater quantity of blood is obtained, and the subsequent oozing from the leech-bites generally prevented. As the blood flows, the exhaustion should be gently continued until the cup is full, when, if it is thought necessary to obtain more, the cup should be re-applied, and its margin surrounded with a cloth dipped in warm water; this causes a copious flow of blood.

In all cases it will be well to avoid, as far as possible, the oozing hemorrhage of leech-bites, as this exhausts the patient without any corresponding influence on the disease, and keeps him in an uncomfortable state. It is much better to make several applications of leeches successively, and to arrest the hemorrhage after the leeches have fallen off, either by the cupping-glass or the application of styptics, of which the best appear to be the solid nitrate of silver, or the muriated tincture of iron. In the Meath Hospital the application of powdered alum has been found very beneficial. After the hemorrhage has been completely arrested, the patient will derive great advantage from the application of warm poultices of linseed-meal or bread and milk over the affected organ; these, however, must be made light, as their weight in some cases proves distressing.

It has been the practice on the continent, and lately in Great Britain, to apply leeches to the anus in case of hepatic irritation, on the principle of depleting the system of the *porta* through the hemorrhoidal veins. We believe that the only cases in which this practice would be decidedly beneficial are those where the hepatitis is complicated with dysentery, or where it has supervened on the suppression of a hemorrhoidal flux; but in no instance should we be content with this mode of local depletion, as it is decidedly inferior to the application of leeches over the affected organ itself. In the dysenteric complication to which we have alluded, which is frequent in India, Mr. Annesley has found decided benefit from the application of leeches to the os coccygis.

The circumstances which point out that the general and local depletions have exercised a salutary influence on the suffering organ are the following:—the diminution of the inflammatory heat and of the oppression in the epigastrium and hypochondrium; the subsidence of the pain and tenderness; and, lastly, of the tumefaction, which is to be ascertained by the touch and by percussion of the lower part of the thorax and abdomen. (See article Abdomen, Explanation of.) Blisters may be now employed, but their use must never be resorted to while the inflammatory fever continues high, and they must be removed as soon as the patient begins to feel their stimulus. (See Derivation.)

When the disease occurs in persons of a broken-down constitution, and particularly in those who have long indulged in ardent spirits, it is scarcely necessary to observe that we must be much more cautious in the use of the lancet, and trust principally to local bleeding and counter-irritation.

After the employment of general and local bleeding, the production of ptyalism appears to be the most powerful means of subduing the disease; but, as we stated before, the practitioner must consider this treatment as secondary to that which has now been pointed out. There can be no doubt that the establishment of a free salivation is commonly followed by a rapid subsidence of the local disease, but it is also true that the accomplishment of this is commonly difficult, and often impossible. The more severe the disease, the greater will be the difficulty of inducing ptyalism; and the best mode of insuring the kindly action of mercury will be to reduce the inflammatory condition of the organ as far as possible before its exhibition. We have before stated the remarkable fact that in cases of suppuration of the liver it has been found nearly impossible to induce salivation.

It would appear that the safest mode of using mercury in this disease is by the exhibition of large doses of calomel at long intervals of time, as it is stated upon high authority that the remedy is thus much less apt to irritate the bowels, and that a less quantity of mercury, when thus exhibited, will sooner affect the system than a greater quantity given in divided doses. Ten grains of calomel, combined with one or two of opium, may be given twice in the day, or a scruple dose at bed-time, as recommended by the East India practitioners. It is stated that the combination of the calomel with some antimonial, such as the antimonial powder or James's powder, assists in

the speedy production of ptyalism. But of one fact we feel certain, that if after the use of mercury for three or four days free ptyalism be not induced, the remedy should be omitted.

In the acute stage of the disease the patient must be kept on a strict antiphlogistic regimen. Effervescing draughts may be allowed, and will often be found to be of great benefit when they act on the skin or kidneys. Mild saline purges with emollient injections should be employed; and the patient may drink a solution of cream of tartar or tamarind tea; and if there be much restlessness, an anodyne draught or twelve grains of Dover's powder should be exhibited at night.

But if, notwithstanding these means, the tumefaction continues, and the fever assumes a remittent or hectic type, the formation of abscess is to be dreaded. Under these circumstances we can no longer push the strict antiphlogistic treatment. The patient's strength must be supported by farinaceous and gelatinous foods, and the exhibition of wine in moderation, with vegetable tonics, will be advisable; poulticing must be diligently employed over the region of the liver, and we must endeavour to bring forward the abscess towards the surface as much as possible; when, in the event of a perceptible and fluctuating tumour being formed, it will be advisable to give exit to the matter as speedily as possible. This, however, is an operation of the greatest importance, and must never be undertaken without a full knowledge of the pathological relations of this disease.

We have already alluded to the rarity of adhesions between the surfaces of the peritoneum in cases of acute hepatic abscess. It is obvious that for the success or safety of the operation the adhesions of the peritoneum is a necessary condition; for in the event of their not existing, the matter will make its way into the peritoneal cavity, defeat the object of the operation, and almost inevitably destroy life. To obviate these difficulties, Dr. Graves has proposed a mode of proceeding which has been repeatedly acted on with success in the Meath Hospital. It is, without question, a most important addition to the surgery of the abdomen. In the fourth volume of the Dublin Hospital Reports this eminent and scientific physician has published a case of hepatitis, in which, notwithstanding the employment of active measures, evidences of suppuration occurred. There was no distinct pointing of abscess, so that it was judged impracticable to perform any operation which could reach the contained matter. Under these circumstances Dr. Graves, reflecting on the fact that certain deep-seated collections of matter may be induced to point towards a situation in which the resistance of the integuments and fascia is removed, proposed that an incision should be made over the most prominent part of the tumour, and carried through the abdominal muscles, so as to reach without dividing the peritoneum. This wound was kept open by plugs of lint, and poultices were applied over it. In a few days after a fit of sneezing by the patient, puriform matter in great quantity broke through the wound. The discharge continued copiously for a number of days, and the patient recovered perfectly.

We have since witnessed two instances where this operation proved successful. It would appear that it not only acts on the principle of removing resistance in a particular point, but also by inducing adhesions immediately below the wound, in all probability the result of its immediate irritation. In a case where numerous abscesses existed, and in which this operation was performed over the most prominent part, we found on dissection that the only point of adhesion of the whole peritoneal surface was that immediately below the wound, and corresponding exactly to its extent. Here recent coagulable lymph was effused, so that there can be no doubt that, had the patient lived longer, the contents of this abscess at least would have been evacuated through the external opening. The operation has every thing to recommend it; it is perfectly safe, productive of no distress to the patient, prevents the chance of effusion into the abdomen, and has been *proved* to be efficacious.

In a case of extensive and chronic hepatic abscess with great attenuation of the integuments, we proposed the performance of this operation; but it was determined by the attending surgeon to try the operation of a caustic issue in place of that proposed by Dr. Graves. After the separation of the slough, the matter did not show any disposition to escape. A small valvular incision was then made through the ulcer, which gave exit to a few ounces of puriform matter. This operation was immediately followed by excruciating pain in the abdomen and the most violent peritonitis, evidently arising from the escape of matter into the cavity, and proving that in this case the operation of the caustic had failed in producing adhesions.

When the abscess makes its way either externally or into the lungs or digestive tube, the strength of the patient must be carefully supported by light and nutritous diet, wine and tonic medicines, according to the circumstances of the case. The mineral acids may also be exhibited in the different tonic infusions, such as gentian, calumbo, or cinchona. Attention must be paid to the bowels; and it seems not impossible but that a gentle and graduated pressure on the organ might accelerate the cure by inducing a closure of the opening after the matter had been evacuated. The opening of the abscess into the serous cavities appears at first sight a necessarily fatal occurrence; and we believe that it has been so in every recorded case, with a single exception. In the report of the Meath Hospital before alluded to, a case is recorded in which death from the peritonitis was apparently prevented by the opiate and stimulating treatment first proposed by Dr. Graves in certain cases of peritonitis. In the case also of double abscess of the liver which we have recorded in this article, the patient lived for eight days after the rupture of the second abscess into the peritoneum, and it was evident on dissection that the process of cure had commenced, the gelatinous effusion in many places having assumed an appearance of layers, and presenting large blood-vessels in its interior.

In the treatment of *chronic hepatitis* the first great indication is to remove all unnecessary stimulation of the liver or gastro-intestinal surface. Fermented liquors and all kinds of stimulating food must be inhibited, and the diet of the patient

must consist of the simplest and most bland articles. The bowels are to be diligently but mildly acted on by gentle laxatives combined with mercurials, such as the hydrargyrum cum cretâ or the blue pill. In the commencement of the treatment we should apply every third or fourth day a dozen of leeches to the region of the liver, until we remove as far as possible the pain and tenderness of the organ. When this is effected, we should resort to counter-irritation, which must be persevered in for a considerable length of time. The best mode of proceeding is by the repeated applications of blisters over different parts of the organ, and by keeping up an eruption with a mild tartar-emetic ointment. If these means do not succeed, and if there is no contra-indication, it will be advisable to affect the system gently with mercury, which may be done either by the exhibition of a small dose of calomel and blue pill combined with Dover's powder, at night, or by mercurial inunctions practised over the region of the liver.

Where it is thought unadvisable to use mercury, from the constitution of the patient, the nitro-muriatic acid and the nitrous acid have been strongly recommended. It would appear that the best mode of using these remedies, particularly the first, is by the external application, either by sponging the surface, or by the foot-bath. The following is the mode in which this remedy is recommended to be used by Mr. Annesley. A mixture is made of eight ounces of pure water with four ounces of the nitric and four of the muriatic acid, of the strength of the London Pharmacopœia. Of this solution from two to five ounces are to be mixed with about three gallons of water at the temperature of 96°, in a high and narrow vessel, and the feet kept immersed in it for about half an hour every night before retiring to rest. If the bath does not cause a prickling sensation in the parts, the next is to be increased in strength. Advantage has also been obtained from sponging the trunk with a similar solution every night. The dilute nitrous acid drink has also been strongly recommended in cases of chronic hepatic affections. It possesses the property of producing a slight salivation, but is much slower in its operation than mercury. Taraxacum is a favourite remedy with many practitioners in these cases, but we are sceptical as to its efficacy.

After the disease has been subdued, vegetable tonics may be given to restore the digestive powers. The patient should wear warm clothing, and carefully avoid any error of regimen that may cause a return of the hepatic disease. In some obstinate cases we have known decided benefit from the use of the seton; and it is scarcely necessary to observe, that where the disease has supervened in a warm climate, removal to a more temperate region will be always advisable.

LUMBAGO. (See Rheumatism.)

LUMBRICI. (See Worms.)

[LUPUS. (See Noli Te Tangere.)

MAGNETISM, (ANIMAL). (See Somnambulism.)]

MALARIA and MIASMA. The first of these words, and that which is now generally employed to designate a certain effluvium or emanation from marshy ground, we have adopted from the Italian. It is formed from the coalescence of the words *mala* and *aria* (*bad air.*) Miasma is a Greek word (*μίασμα*, from *μιαίνω*, *inquino*, *polluo*,) signifying originally contagion or pollution, but now with the occasional adjunct, marshy, not unfrequently applied to the same effluvium or emanation.

We infer the existence of the matter designated by one or other of these terms, as we do that of contagion in cases of disease which do not furnish a material transferable by inoculation, from certain effects on the animal economy; and we trace its origin to marshes from its having been observed, for a series of ages, that such effects are produced only in the vicinity of marshes, or at least are more abundant where vegetable matter and water are so situated with respect to each other, that a chemical reaction between them is possible. The observation of centuries having rendered us well acquainted with certain effects of malaria, we now reason conversely; and when we perceive the more familiar of them, particularly intermittent and remittent fevers, we infer its existence, and endeavour to discover its sources, which may not be very manifest.

The chemical and physical properties of malaria are unknown to us; the experiments which have been hitherto performed to illustrate its nature, or even to discover its presence, having furnished very unsatisfactory results. The air collected above the marshes of fort Fuentes was found by Gattoni as pure as that at the summit of Mount Leguone, if not more so; and M. Deseye obtained in the most confined marshes as on the most exposed hills, 78 parts of azote, 21 of oxygen, and one of carbonic acid, from an analysis of the air. It is true that MM. Thénard and Dupuytren found that the carburetted hydrogen gas disengaged from marshes left in the water through which it was passed a peculiar and very putrescible matter; and M. Julia discovered that dew gathered in the neighbourhood of marshes contains, likewise, a matter capable of fermentation; but there is no evidence that these substances are malaria; nor, were they proved to be so, do we know anything of their chemical properties but their capacity of undergoing the putrefactive process. Even the very obvious question, whether malaria is always one and the same, or a multiplicity of marsh poisons exist, is one which the present state of our knowledge does not enable us to answer decidedly. It has been argued that as the existence of such a poison is known only by its effects on the constitution, a variety in these effects should be deemed evidence of a difference in the poison. But it may be remarked that the diseases which are reputed to originate from malaria pass in the same subject into each other,—intermittents, for instance, into remittents, and inversely; and that, of a certain number of individuals residing in or merely visiting the same place at the same time, and consequently exposed to the same morbific cause, some are attacked with one form of fever, others with another. And we know that diseases certainly derived from one and the same poison, such as small-pox, exhibit great diversity of character in different persons. These circumstances favour the opinion that there are no differences in the

effects of this poison which may not be explained by a difference in the dose, or of the constitution on which it acts, or by the influence of certain agents, such as temperature, which modify its operation. The fact most in favour of a multiplicity of poisons is the occasional prevalence of one form of malarious disease, yellow fever for example, in the same situation for months, to the exclusion of all others. But as this occurs only under high temperatures, which at once promote the evolution of the poison, and modify the individual habits on which it operates, we would not consider it to furnish conclusive evidence, that the poison acting in this case is specifically different from the malaria which produces other forms of marsh fever.

[Of late, an attempt has been made by Professor Daniell to show, that sulphuretted hydrogen gas is the pestiferous agent: but as the notion has been exploded under the results of observation, it is unnecessary to dwell upon it.]

From what we have said on this obscure branch of our subject, it will be tolerably manifest that on the questions of the nature and simplicity or variety of malaria we possess no satisfactory information whatsoever; and that the legitimate objects of our present investigation are its sources, the laws of its propagation, the extrinsic circumstances which modify its influence, its effects on the animal economy, and the measures to be adopted to guard against these effects.

Though marshes, whether salt or fresh, are prolific sources of malaria, especially in a certain stage of the drying process under a hot sun, this poison is the product besides of various sorts of soil, to which the term marsh is by no means applicable. In the warmer regions of the earth these collections of low and dense brushwood, or of reeds and grass which are called *jungles*, are so familiarly known to be productive of malaria, that jungle-fever is as common a name for malarious disease in southern latitudes as marsh-fevers in Europe; and in the warmer regions of Asia, Africa, and America, even the larger and more open woods generate the poison under certain circumstances. Grounds which are alternately inundated and drained for the cultivation of rice, whether in India or Europe, have been found so injurious to the health of the cultivators and the neighbouring inhabitants, that by some governments, that of Russia for example, this species of cultivation has been prohibited. Wet meadow lands, especially in warm climates, and in temperate ones during seasons of unusual heat, have been proved to be sources of malaria; at least agues have been observed to prevail in districts in which no assignable cause for them existed but lands of this description. That the half-wet ditches of fortifications may produce malaria was shown by the result of filling up those of Bourg-en-Bresse, by which process those fevers ceased which had previously so affected the inhabitants, that one half of them were incapacitated from any occupation for a third of the year. The mud which is left by the drying of extensive ponds or marshes by the summer's heat, though invested at the time with no growing vegetation, but probably containing vegetable and likewise animal recrements, is capable of furnishing this poison. Lakes, especially if situated in flat countries, are indirectly sources of it, not by the moisture of their immediate margins only, but likewise by imparting a degree of the same quality to the adjacent country. Considerable portions of Hungary and tracts of land in France are rendered insalubrious from this cause. The mud left by the retiring tide in sea-ports and estuaries is productive of malaria in hot climates, as is evinced by the fevers with which the crews of boats are attacked in such situations; and we have seen reason to think that in certain seasons they are not perfectly salubrious in our own. The felling of woods, by which process land previously shielded from the sun's rays (and consequently damp) is exposed to their influence, is often followed by the prevalence of malarious disease in the district in which it is performed. Turning up lands which have long laid in pasture for the purpose of cultivating them is mentioned both by Volney and Rush as productive of malaria and its consequences. In the West Indies this has been found to be a very dangerous operation, Cassans describing it as sometimes producing fevers which resemble an absolute plague, the labourers even dying on the spot if they attempt to remain at night on the ground which they have broken up during the day. (*Macculloch* on Malaria, p. 112.)

The decomposition of vegetable matter in other circumstances than in connection with soil has frequently proved a prolific source of malaria. This is often exemplified by the pernicious effects of steeping flax and hemp; and Rush and others mention examples of fevers originating from the decomposition of coffee, potatoes, pepper, and other vegetables. The sickliness of ships from the leakage of sugar in a damp hold, and the occurrence of a fever which committed fearful ravages on the crew of the Priamus frigate from the action of bilge-water on chips and shavings left in the hold from the repairs of the magazine, as mentioned by Burnett, may be referred to the same class. Neglected sewers and drains have proved under a high temperature to be productive of fever by generating this poison.

If the preceding enumeration of circumstances under which the production of malaria takes place be examined, it will be found that vegetable matter and moisture are present in all the examples, and that animal matter is so occasionally. It is a proper subject of inquiry, and one which has given rise to some controversy, which of these elements are essential to the generation of the poison, and under what condition those which are essential should exist to possess the power of producing it.

With regard to water, it seems ascertained that its presence is necessary, if not at the surface, certainly below it; but that the quantity in the former situation should not be large. Many circumstances tend to prove that for the production of malaria only a small proportion of water should exist in any situation. It is remarked by African travellers, that in that country the evolution of malaria commences immediately on the falling of rain, and that of this the inhabitants are so conscious that they then retire to their houses, and endeavour to exclude even the least access of air. As the rains continue and the ground becomes thoroughly wetted, the sickness abates, to be renewed with greater violence on the retiring of the

rains, and the ground becoming dry. In the case of inundations, it is at their subsidence that sickness prevails, as was exemplified by the mortality among our troops under such circumstances during the Burmese war. In temperate climates, a marsh, the whole surface of which is thoroughly wet, is comparatively innocuous; but if partially or entirely dried by the summer's heat, it becomes extremely pestilential in autumn. Dr. Ferguson, a writer whose extensive opportunities have been aided by great power of observation, has furnished us with many instances, we cannot so justly say, of the small degree of moisture as of the excessive dryness which produces malaria in its most intense degree. "The army," says this writer, "advanced on to Talavera through a very dry country, and in the hottest weather fought that celebrated battle, which was followed by a retreat into the plains of Estremadura, along the course of the Guadiana river, at a time when the country was so arid and dry for want of rain, that the Guadiana itself and all the smaller streams had in fact ceased to be streams, and were no more than lines of detached pools in the courses which had formerly been rivers; and there they suffered from remittent fevers of such destructive malignity, that the enemy and all Europe believed that the British army was extirpated. The aggravated case of the disease differed little or nothing from the worst yellow fevers of the West Indies; and in all the subsequent campaigns of the peninsula, the same results uniformly followed, whenever, during the hot season, any portion of the army was obliged to occupy the arid encampments of the level country, which at all other times were healthy, or at least unproductive of endemic fever."* The writer can vouch from personal observation for the accuracy of this description; and he has repeatedly observed that cases of fever and ague abounded in parts of Estremadura so remote from the Guadiana or any stream, that no influence from visible water or dampness could be supposed to have a share in their production.

The following example taken from Dr. Ferguson's paper is strongly illustrative of the same facts, the effects of concealed water in producing the poison. The approach to the town of Ciudad Rodrigo is through a bare, open, hollow country, that has been likened to the dried-up bed of an extensive lake. Upon more than one occasion, when this low land, after having been flooded in the rainy season, had become as dry as a brick ground, with the vegetation utterly burnt up, there arose fevers among our troops, which, for malignity of type, could only be matched by those before mentioned on the Guadiana.

It will be readily understood, that though the surface of the soil which produces fever may appear dry or even burnt, yet as its occurrence takes place after rains, there is no proof that the presence of moisture is not necessary, but evidence of the very reverse, though it is shown that the dampness need not exist on the surface. The nature of the sub-soil, — its being, for instance, a dense clay, which by preventing percolation may detain the water within a short distance from the ground,—has probably some influence in engendering sickness; but there are many facts which prove that an impermeable subsoil is by no means essential to the production of the poison. The leeward shore of Guadaloupe, Dr. Ferguson informs us, so far from being impermeable, is a remarkably open and pure one, being mostly sand and gravel, altogether without marsh in the most dangerous places; yet it is inconceivably pestiferous throughout the whole tract. The soil of Walcheren, too, of the pestilential nature of which we have had such melancholy experience, is sandy, or a mixture of clay and sand.

These examples tend to confirm, so far as the water is concerned, the law of Dr. Ferguson, that the only condition indispensable to the production of the marsh poison on all surfaces capable of absorption is the paucity of water where it had previously recently abounded; a rule, to which he assures us there is no exception in climates of high temperature. It ought at the same time to be remarked, that though the formation of malaria is perfectly compatible, as the writer can testify from personal observation, with the degree of superficial dryness described by Dr. Ferguson, it may likewise consist with a degree of manifest moisture.

The necessity of the presence of vegetable matter has hitherto constituted an important part of the creed regarding malaria, but this necessity is questioned in the paper in the Edinburgh Philosophical Transactions, to which we have so often adverted. We have already mentioned Dr. Ferguson's opinion, that the only essential requisite for the formation of the poison is, that water should be absorbed by soil and then exposed to speedy evaporation; and the following example is given of the apparent absence of vegetable matter from a situation abundantly productive of malaria. "In Spain, during the month of May 1809, which was cold and wet, the army remained healthy; but in June, which was remarkably hot and dry, marching through a singularly dry rocky country of considerable elevation, several of the regiments bivouacking in hilly ravines which had lately been water-courses, contrary to the advice of officers who had served in the Mediterranean, several of the men were seized with violent remittent fever, (the first that had shown itself in the march,) before they could move from the bivouac the next morning; and this portion of the troops exclusively were affected with this disorder for some time. In this instance, the half-dried ravine having been the stony bed of a torrent, in which soil never could be, the very existence of vegetables, and consequently of their humid decay and putrefaction, was impossible, and the stagnant pools of water still left among the rocks by the water-course, and near which these men encamped, were perfectly pure. Yet this situation proved as pestiferous as the bed of a fen." Even in this situation, which furnishes the strongest argument that could be adduced for the author's departure from the established creed, it would perhaps be difficult to prove the total absence of vegetable matter, not only from the surface of the ravines, but beneath the rocky surface; and certainly there exist many facts which prove that vegetable matter is in the highest degree favourable to the pro-

* On the Nature and History of Marsh Poison, by Wm. Ferguson, M. D., &c. (from the Transactions of the Royal Society of Edinburgh), Edinburgh, 1821.

duction of malaria, if not essential to it. These are, the universal presence of such matter where the poison is generated, the cases adduced by Dr. Ferguson and similar ones excepted, if they are to be regarded as exceptions; the pernicious effects of the steeping of hemp and flax, for we presume it will not be argued that in this case the mere evaporation of the water, independently of the vegetable matter, would produce the poison; a similar result from the leakage of sugar and the decomposition of coffee, potatoes, pepper, &c., and the fever which committed such ravages on board the Priamus frigate from the action of the bilge-water on the chips and shavings left in the hold. A similar argument may be deduced from the wholesomeness of peat-bogs, which seem as well calculated as any marsh to produce malaria, excepting that the vegetable matter they contain being in a sub-carbonized state is not susceptible of decomposition. Since there is no reason to think that the evaporation of mere water will produce the poison, we are compelled to conclude that, if there was no vegetable matter present in the cases mentioned by Dr. Ferguson, some influence from mere terrestrial soil gave rise to the effects, which are usually owing to the presence of such matter.

The necessity of the putrefaction of the vegetable matter present when malaria is produced, is a different question from that which we have just considered. In by far the greater number of cases in which this poison is generated, there is no offensive smell whatever; it is true that a marsh or other source of malaria may be at once noisome to sense and pestilential, but it is frequently the latter without being the former. Although it has been shown that vegetable decomposition is instrumental in the production of the poison, if not strictly essential to it, yet the circumstance of its being generated in abundance without there being any perceptible smell, and in situations so dry that vegetable putrefaction, in the ordinary sense of the term, seems impossible, appears to prove that this decomposition is either in degree or kind different from putrefaction, though the two may coexist.

Malaria is generated in so many instances in which animal matter does not exist, that we must conclude that the presence of such matter is not essential to the formation of the poison; whether, when present, it increases the quantity or modifies the nature of the miasma, does not appear to be ascertained.

[On the evidences in regard to animal or vegetable putrefaction, or both being the cause of malaria, the writer has entered at great length in his *Human Health*, p. 64, Philad. 1844. He regards the affirmative as by no means proved.]

Heat is the extrinsic agent most influential in favouring the production of malaria in soils and situations capable of engendering it—an influence attributable probably to the effect of a high temperature in favouring the chemical action between organized recrements and humidity, and likewise to its accelerating the formation of the aqueous vapour which appears to be the vehicle of the diffusion of the poison. Hence, even the milder forms of malarious disease are observed only in seasons of a certain degree of warmth, rarely, for instance, arising in this country before the vernal or after the autumnal equinox; whilst the more intense degrees occur only in the higher latitudes, or, if seen in climates ordinarily temperate, it is during seasons of unwonted heat; and whersoever they exist, their prevalence is terminated by the cold of winter. It has often been observed, that a summer of unusual warmth, especially if occurring after a wet spring, causes intermittent and remittent fevers to reappear in districts whence they had long been banished by the improvement of agriculture,—an occurrence, of the possibility of which medical men should be aware; for when the malarious disease has made its visitation in the form of remittent, it has not always been discriminated from typhus, and confusion and controversies have thence arisen, not very creditable to all parties concerned.

The branch of our subject now to be considered, the propagation of the poison, is one regarding which we possess a considerable degree of irregular knowledge, consisting rather of detached facts presenting various unexplained anomalies, than of groups of corresponding facts from which the medical reasoner can deduce fixed and determinate laws. As might be supposed, the effect of the poison is in general more intense in proportion to the proximity to its source. This is probably owing to the more condensed state in which malaria exists near to the spot where it is generated; and it is remarked, that circumstances which favour its condensation add to the intensity of its effects. It appears to be on this principle that the vicinity of swamps is so much more pernicious in the evening or night than during the day. The influence of a high temperature in favouring the production of the poison, has already been pointed out; but it appears that during the portion of the day when the temperature is at its highest, the mobility of the atmosphere is so great, and favours so much the diffusion of the poison, that it is comparatively innocuous near the spot where it is generated; but in the more quiescent state of the air in the evening, though it is less abundantly formed, it is infinitely more pernicious. Its effect at these times is aided probably by its finding a powerful vehicle in the mists, which at night are observed to rest over low and marshy grounds. The more pernicious effect of the night-air in a pestilential country and season, however it is to be explained, is familiarly known, and is often exemplified by the fatality to soldiers of certain night-guards.

But to this general law, that malaria is more pernicious in proportion to the proximity to its source, there are important exceptions. In some instances it is found to affect places at some distance, especially if they are situated on an eminence, with the same if not greater intensity than those in the vicinity; thus the neighbourhood of Versailles is powerfully influenced by the marshes of St. Cyr; and at Neuville-des-Dames, above Chatillon on the Indre, fevers are more prevalent than close to the marshes where the malaria is produced. The stagnant water of Lake Aguano, we learn from M. Monfalcon, exhales deleterious effluvia, which are carried backwards to the north-east to two or three villages, and even to the convent of Comaldules, a league distant, and situated

on a high mountain. But the most extraordinary instance of this kind is mentioned by Dr. Macculloch, as occurring in Malta; the malaria which is produced on the beach beneath a cliff producing no effect on the spot itself, while it affects, even to occasional abandonment, the village situated above.

In explanation of circumstances of this nature, of which it were easy to multiply examples, M. Monfalcon supposes that the aqueous vapours in which the marsh poison is dissolved, are raised during the day by the heat and consequent expansion of the air, and are condensed and precipitated on the adjacent hills during the evening; whilst Dr. Ferguson conceives that so far from rising into the atmosphere, malaria has a peculiar attraction for the earth's surface, along which it creeps so as to concentrate and collect on the sides of the adjacent hills. We doubt whether either of these explanations is very satisfactory, and think it probable that the explanation of these facts is to be found simply in currents of air which sweep the surface of the marsh, so as to prevent the accumulation of the emanations there, and convey them in a state of condensation to the more elevated spots situated in the line of the atmospheric movements. The situation of certain elevated places, which have been powerfully influenced by marsh emanations, has frequently been observed to correspond with the direction of a manifest current of air which passed over the surface of a swamp. Chains of hills in Corsica and Italy, very far from morasses, but placed in their line, and in the face of a wind which carried to them their emanations, were entirely depopulated and rendered uninhabitable. Orlandi cites an analogous example: — the south winds passed over stagnant waters before arriving at some hills, the air of which they infected: these heights became salubrious only when Pope Paul V. had caused the marshes to be drained.

The distance to which marshy emanations may extend by gradual diffusion, has been calculated by Monfalcon to be 1,400 or 1,600 English feet of elevation, and from 600 to 1000 in a horizontal direction. In Europe these limits, he supposes, cannot be exceeded; but in equatorial regions the activity of the poison is much more extended; and in the West Indies, vessels at the distance of 9,000 feet from the marshy coast have felt their baneful effects. But when winds are in operation, their influence may extend to much greater distances than those mentioned. The case of the convent of Comaldules, which was infected at the distance of three miles, has already been quoted; but we know not any facts which teach us the extreme limits to which the poison may be transported. The distance will probably be influenced if the ground be such as to preserve the poison in a state of condensation instead of allowing it to be diffused; thus, a current of air sweeping up a valley, at the mouth of which the surface is swampy, will convey the poison to a greater distance than it could reach in a more open situation. An instance of this kind occurs in Ceylon, where the poison is conveyed many miles inland up a valley, whenever the sea-breeze blows in such a direction as to cross the swamps on the shore and enter its mouth.

We should take but an imperfect view of malaria did we consider intermittent and remittent fevers its sole results. Besides these its more familiar effects, organic affections of the spleen, liver, and mesenteric glands; similar affections of the stomach and intestines; dropsy, apoplexy, palsy, and idiocy, as manifested in the marshy districts of Tuscany, and in the cretinism of the valleys of Switzerland, are the effects of its long-continued application. Cholera, dysentery, and diarrhœa, are by many writers referred to its more brief agency, and there is reason to think occasionally with justice; intermittent neuralgia, there seems little doubt, is one of its effects, and to this formidable list some are disposed to add rheumatism, but the propriety of this seems doubtful. It is observed that the natives of marshy districts, who permanently reside in them, lose their whole bodily and mental constitution, contaminated by the poison they inhale. Their aspect is sallow and prematurely senile, so that children are often wrinkled, their muscles flaccid, the hair lank, and frequently pale, the abdomen tumid, the stature stunted, and the intellectual and moral character low and degraded. They rarely attain what in more wholesome regions would be considered old age. In the marshy districts of certain countries, for example Egypt, Georgia, and Virginia, the extreme term of life is stated to be forty; whilst we learn from Dr. Jackson, that at Petersburg, in the latter country, a native and permanent inhabitant rarely reaches the age of twenty-eight. [Dr. Jackson's remark must have been made, however, on inadequate statistical evidence, and probably on no statistical evidence whatever. If it were ever correct, it is utterly inapplicable to the Petersburg of the present day.] In the portions of Brittany which adjoin the Loire, the extreme duration of life is fifty, at which age the inhabitant wears the aspect of one of eighty in a healthier district. It is remarked that the inferior animals and even vegetables partake of the general depravation; they are stunted and short-lived.

By the progress of civilization, and consequently of agriculture, the domain of malaria is diminishing throughout the more enlightened portions of the earth. This is manifest in our own country, from many parts of which, where they formerly prevailed, agues have been banished. The draining of swampy lands; preventing in ponds or other damp situations the accumulation of putrid or putrescible vegetable or animal matter; and, in marshes situated near the sea, preventing by embankments the mixture of salt water with fresh, from which combination most pestilential emanations have always been observed to proceed, are the most efficient means of reclaiming malarious tracts, and consequently of preventing the production of the poison. But some lands are of so incorrigible a nature, the Pontine marshes for example, that the hand of man has hitherto been employed upon them in vain; and it is desirable to know, since we cannot prevent such districts from generating the poison, how its diffusion and pernicious influence may be in some degree checked. It is remarked that malaria has a peculiar attraction for certain surfaces, and that it is not disengaged from those to which it adheres, at least not in a noxious form; in other words,

they do not constitute fomites. The attraction of the poison for trees is great; and it has repeatedly been observed that not merely a few individuals, but the population of whole cities, situated in the most swampy districts in the world, have owed their security to a screen of woods interposed between them and the marshes. Facts of this nature suggest very obviously the propriety of planting trees in the vicinity of irreclaimable swamps. The floors of dwellings are supposed to have a similar attractive power over the poison; and hence, in malarious districts, the second stories of houses are found to be more salubrious than the first; and if from circumstances the first floor must be occupied, some security is afforded by having the bed a few feet elevated from it.

Nutritious diet, and that kind of general regimen which is most conducive to good health, should be observed by individuals exposed to the operation of malaria; and they should be especially careful to avoid, if possible, the vicinity of swamps in the evening.

MEDICINE, (HISTORY OF*) — CHAPTER I.—*Introduction—Division of the history of medicine into three great chronological periods — History of medicine previously to its introduction into Greece—Origin of medicine — State of medicine among the Egyptians — Among the Assyrians — Among the Jews—Introduction of medicine into Greece—Chiron — Æsculapius — Machaon — Podalirius—The Asclepiades—Records in the temples of Æsculapius — Ancient inscriptions — Pythagoras—Democritus—Heraclitus—Acron — Herodicus—Gymnastic medicine.*

Although the primary object of this treatise is to present a view of the history and progress of practical medicine, yet it will be impossible to avoid entering occasionally into the consideration of the various theories and speculations which have so generally prevailed in the science. Medical theory and practice have been so intimately blended together, that it would be useless to attempt to separate them. The terms which are employed, in works of the most practical nature, are, for the most part, derived from the theory which was current at the time of their publication, and even the narrative of facts and the direct details of experience are, with a few exceptions, deeply tinged with the prevailing doctrines of the day, or with the individual speculations of the writer. Those who are versed in medical science, and who are acquainted with the relation which it bears to the other physical sciences, with the mode in which it is acquired, and the nature of the evidence on which it rests, will easily perceive that, in this department, it is peculiarly difficult to separate facts from hypothesis. It may, however, be asserted, that until this be accomplished, medicine can never be placed upon the basis of induction, and that this alone can give it that stability, which may entitle it to be regarded as a correct science. In its present condition it will be impossible to do more than to approximate to so desirable a state, but it will be a special object of attention, in the following pages, to endeavour to point out the limits between practice and theory, between facts, and the opinions that have been deduced from them.

When we take an extended view of the progress of medicine, tracing it from its scanty sources, in the most remote periods of society, and observe its course, as gradually augmented by the stores of Grecian and Roman learning, obscured by the darkness of the middle ages, and again bursting forth in the copious and almost overwhelming streams of modern literature, we are naturally led to separate the narrative into three divisions, corresponding to the three great chronological periods. The first of these will comprehend the history of practical medicine, from the earliest records which we possess, to the decline of Roman literature; the second will contain an account of the state of the science, through what are termed the dark ages, until the revival of letters; the third will commence with the establishment of the inductive philosophy, and be continued to the present time.

In tracing the history of this science from its earliest records, it will not be necessary to devote much time to a subject, which was formerly discussed with great learning and acuteness, viz. the origin of medicine. It may be sufficient to remark that, in proportion to the progress of civilization or refinement, attempts would be made to remove or alleviate the diseases, and to repair the injuries, to which the body is constantly incident. Subject as it is, at all times, to the influence of various noxious agents, and to a consequent derangement of its functions, to painful affections of various kinds, and to the loss or depravation of its powers or actions, we must conceive that mankind would be anxious to remove or relieve these evils. The means that would be employed must have been, in the first instance, extremely imperfect, and frequently ill directed. They may have been suggested by the effects of certain kinds of food, or by the operation of certain external agents on the body: some analogies may have been derived from the spontaneous actions of the system, by observing the natural efforts of the constitution to remove certain causes of disease, or to relieve the patient when suffering from their effects. Thus, in the earliest periods of society, mankind must have been aware of the relief which was obtained, in the derangements of the alimentary canal, by an evacuation of its contents, and would probably have discovered, incidentally, that certain vegetable substances promoted this operation. In the external injuries to which the body is subject, more especially in a rude state of society, means would early be had recourse to for procuring present ease from pain, or for removing the obvious danger to life, which would so frequently follow from various causes. It would soon be found that the pain was diminished by

* The writer of this Essay begs to remark that the references inserted at the foot of the page are to be regarded as the authorities for the facts and dates contained in the text; with respect to the opinions that are maintained, he is to be considered as alone answerable for them. Where he has conceived it necessary to dissent from, or to controvert, the doctrines of his predecessors, he has endeavoured to do it without acrimony or arrogance, and he trusts that his remarks will be received with the same spirit of candour in which they are offered. He thinks it necessary to state that wherever a reference is made to any book, the book so referred to has been examined by him.

excluding the wounded part from the air, or from other extraneous substances; that by certain modes of pressure, the flow of blood might be restricted; and that, in some cases an increased, and in others a diminished temperature, gave immediate ease to the patient, and tended to promote the ultimate cure. A rude species of medical and surgical practice of this description has been, in all cases, found to exist in newly-discovered countries, even when in the most barbarous state; while it has been observed generally, that the improvement in the healing art has been nearly in proportion to the advancement of the other arts of life, and to the gradual progress of knowledge on all subjects intimately connected with our existence or welfare.

The historical records which we possess respecting the progress of practical medicine are scanty and uncertain; but, so far as they extend, they coincide with the view of the subject taken above. The writers who have investigated this point with the greatest learning and assiduity inform us, that Egypt was the country in which the art of medicine, as well as the other arts of civilized life, was first cultivated with any degree of success, and that it had advanced so far as to have become a distinct profession. We are not, however, informed in what degree or to what extent that distinct appropriation was carried; whether medicine was made the exclusive business of certain individuals, who were regularly instructed for that purpose; whether it was attached to certain public functionaries, especially to the priests; or whether persons in different situations applied themselves to the practice of medicine, from a real or supposed superiority in their skill and in their knowledge of the treatment of diseases. The probability, however, is that the priests of the Egyptians were at the same time their physicians. This appears to have been the case among the Jews and the Greeks, who are supposed to have borrowed from the Egyptians many of their institutions; and indeed it seems to be the natural progress of society in its earlier periods, when the priests were generally the depositaries of knowledge of all kinds, and when they confined it as much as possible to their own use, for the purpose of maintaining their influence over the rest of the community.

From some remarks which are made incidentally in the Mosaic writings respecting the learning of the Egyptian priests, it would appear that it consisted, in a great measure, of the employment of magical incantations, and, so far therefore as it effected the cure of disease, must have operated through the medium of the imagination. This has been, in all cases, the first step in the art of medicine, if it may be so called, and its efficacy must have been in exact proportion to the ignorance and superstition of the people on whom it was exercised.

A circumstance respecting the practice of medicine in Egypt is mentioned by Herodotus, as existing when he visited that country, and which, it may be presumed, was transmitted from a much earlier period, that certain individuals treated certain diseases only. (Euterpe, sec. 84.) This division into separate branches might, at first view, seem to indicate a considerable progress in the practice of medicine, and it may undoubtedly have led to a degree of manual dexterity and of minute observation in certain departments. But, independent of any other consideration, we may rest assured, that the science must have remained in a state of complete degradation, when we bear in mind that it was the custom in Egypt, as it is in the present day among many of the nations of the east, to transmit the same occupation from father to son, through a number of successive generations. This practice, although it may be favourable to the perfection of an art, or even of a science, in some of its minute details, must furnish an almost insurmountable obstacle to its general improvement, or to the development of the powers and faculties of the human mind.

Although we are in the habit of considering Egypt as the parent of the arts and sciences, the empire of Assyria has been supposed, by many learned men, to possess a greater claim to this distinction. Perhaps the priority of invention may be justly awarded to the Assyrians, but the memorials which they have left behind them are so scanty, that the degree of excellence to which they arrived is almost entirely conjectural. The priests of this nation, as in all other cases, appear to have been the depositaries of all the learning of the times, and of that of medicine among the rest. We have reason to suppose that their practice consisted of little more than the dexterous application of magical arts, and such other means as tended to impress the minds of the people with a sense of their power over the operations of nature, while any actual information which they possessed was carefully concealed under the guise of mystery and superstition. (*Herodotus*, Clio, passim; *Enfield's* Hist. of Phil. v. 1. p. 25 et seq.)

In the writings of Moses there are various allusions to the practice of medicine among the Jews, and more especially with regard to the treatment of leprosy. The priests appear in this, as in other cases, to have been the practitioners; the treatment consisted principally in certain regulations for the purpose of promoting cleanliness and preventing contagion, together with various ceremonies, which, so far as they could affect the patient, must have acted entirely on the imagination. (Leviticus, chap. xiii.-xv.) So little is known respecting the state of the arts and sciences in the other countries of the east, at these remote periods, that it is scarcely necessary to allude to them in this place. We shall only remark that the imperfect and scanty notices which we possess on this subject would lead us to conclude, that the practice of medicine was even in a less advanced state than among the Egyptians, its progress being regulated by the greater or less degree of refinement or civilization of the respective countries, but in no case having advanced beyond the state of implicit credulity and gross superstition.*

* For further information respecting the state of medicine among the Egyptians and the other nations of antiquity, previously to the Greeks and Romans, the reader is referred to the following works. *Herodotus*, Euterpe et Clio, passim. *Diodorus Siculus*, lib. i. sect. 25, 82. *Plinius*, lib. vii. cap. 56, lib. xxix. cap. 1. *Plutarchus*, De Iside et Osiride. *Josephus*, Antiq. Jud. lib. viii. cap. 2, sec. 5. *Clemens Alexandrinus*, a Potter, Stromat. lib vi. p. 758. *Conring*. Introd. Art. Med. cap. 3, sec. 2, et De Hermet. Med. passim. *Barchusen*, Diss. No. 1, et 7

After having given an account of the state of medicine among the ancient Egyptians and other contemporary nations, as far as can be gleaned from the scanty records that remain on this subject, we must follow it into Greece, and trace its progress from the period of its first introduction in the remote and semi-fabulous ages of their *demigods* and *heroes*, until it acquired the rank of a science under the genius of Hippocrates. It is generally admitted, that although Greece cultivated the arts and sciences with so much success, yet, in the first instance, she borrowed them from the neighbouring nations; principally, as it would appear, from Egypt, and in some cases from Phœnicia. (Vide *Bryant*, ubi supra, et v. 2, p. 426 et seq. et alibi.) To certain individuals who migrated from these countries, the Grecks themselves were in the habit of referring the introduction of many of the most useful inventions, and during a considerable space of time all those who were desirous of acquiring a larger share of knowledge, either theoretical or practical, than was possessed by their countrymen, visited Egypt, as the great storehouse of science and learning. It is from this cause that we find so much analogy between the divinities that were worshipped in the two countries, as inventors or patrons of the various arts and sciences. For although they acquired new names on their being transferred into Europe, yet their attributes, and even their forms, clearly demonstrate their origin. This is particularly the case with respect to medicine, so that in the Orus and Thouth of the Egyptians we may recognise the prototypes of the Apollo and Hermes of the Greeks. (*Haller*, Bibl. Med. Pract. lib. 1, sec. 7, 8. *Hundertmark*, in Ackermann, Opuscula, Exerc. No. 1.)

It is not until comparatively at a late period, approaching to that of the Trojan war, that we find the names of actual personages who practised medicine in Greece; and of these, it is probable that some were natives of either Africa or Asia, who brought with them the information which they had acquired in their respective countries. Of those whose history is better known, and who were acknowledged to be of Grecian origin, it was the general custom to travel into Egypt for the purpose of obtaining a knowledge of their art, and with this view they submitted to a system of rigid discipline, and to a variety of irksome and burdensome ceremonies; and after all this laborious process, so far as the science of medicine is concerned, the result seems to have been little more than the knowledge of magic and incantations, with some rude notions respecting the application of external remedies for the cure of wounds and of cutaneous diseases, with a very imperfect idea of the anatomy of the human body, and a very inadequate conception of its functions. (*Herodotus*, Euterpe, passim. *Diodorus Siculus*, lib. 1. passim. *Josephus*, Antiq. Jud. lib. viii. cap. 2, sec. 5. Odyss. xix. 656 et seq. Æneis, vii. 753 et seq.)

The first native of Greece who is more particularly singled out, as having introduced the art of medicine among his countrymen, is the centaur Chiron. There is much mystery attached to his character and to every thing connected with him, but what we may consider as the most probable conclusion is, that he was a prince of Thessaly, who lived about the thirteenth century before the Christian æra; that he was distinguished above his contemporaries for his knowledge of the arts of life, and that, after the manner of his countrymen, he was frequently seen on horseback, so as to give rise to the fabulous account of his compound form. He is particularly celebrated for his skill in medicine and in music, a combination, it may be remarked, that was said to have existed in many other individuals. We are not informed by what means he obtained his superior knowledge in medicine, but there are various circumstances, which lead us to conclude, that it was at that time regarded rather as a part of the education of all men of rank, than as attached to a particular profession. We accordingly find that he instructed the Argonauts in medicine, and the heroes who were engaged in the siege of Troy, and that all the kings and warriors of that period were more or less acquainted with the treatment of wounds, and even with the practices which were adopted for the cure of internal diseases. (Ilias, xi. 636 et seq. *Sprengel*, t. 1, p. 112, 13. *Ackermann*, per. 1, cap. 3, sec. 25—40.)

But although Chiron has the reputation of having introduced the art of medicine into Greece, it is to his pupil Æsculapius, that by the common consent of antiquity, is ascribed the merit of having first devoted himself to the cultivation of medicine as a science, and of having made it a distinct object of pursuit. The improvements which he made in the art were so considerable, as to have induced his countrymen, after his death, to pay him divine honours, to designate him as the god of physic, to erect temples to him in various parts of Greece,* and to derive his origin from Apollo himself. His history, when divested of all the fabulous appendages that were attached to it by his contemporaries, appears to be that he was a native of Epidaurus, that he was exposed in his infancy, probably in consequence of his illegitimate birth, that he was accidentally discovered by a shepherd, and placed under the care of Chiron. His death was said to have been caused by the jealousy of Pluto, in consequence of the number of individuals whom he rescued from the grave; from which tale we may at least conclude that his reputation as a successful practitioner must have been much higher than that of any of his contemporaries.†

According to the custom of that age, he trans-

mitted his profession to his sons Machaod and Podalirius, who accompanied the Greeks in the Trojan expedition, and are celebrated in various passages of the Iliad for their medical skill.* From the incidental mention that is made by Homer and the early Greek writers of the nature of the remedies that were employed by these individuals or their contemporaries, it will appear that their practice was principally surgical, and nearly confined to the treatment of wounds, and that, with respect to internal diseases, they were for the most part conceived to be the immediate infliction of the Deity, and were therefore abandoned as incurable, or at least were to be obviated only by charms and incantations, and that the arts of magic formed no inconsiderable part even of their surgical practice. (Ilias xi. 636 et seq. Odyss. xix. 456 et seq.)

The practice of medicine remained for a considerable time hereditary in the family of Æsculapius, and in a great measure confined to it. His descendants obtained the name of Asclepiades; they were the priests of his temples, and presided over and directed the rites and ceremonies.—(*Sprengel*, t. i. p. 168 et seq.) These temples, indeed, became a species of hospitals, to which patients resorted from all quarters for the relief of the diseases with which they were affected. Under the direction of the priests of these temples they underwent a variety of ceremonies, the immediate effect of which must have been principally upon the imagination. Some, however, of the practices which were enjoined were of a dietetic nature, and were directly conducive to temperance and cleanliness; such as frequent ablution, and the abstaining from certain kinds of food. To these if we add that the temples were generally erected in healthy situations, that the patients enjoyed rest and leisure, and that the mind was interested by a succession of new and pleasing impressions, we may suppose that they would be placed under circumstances, not a little resembling those which are found so conducive to health by the invalids who frequent the medicinal springs and other analogous establishments of modern times. (*Clerc*, part i. liv. ii. ch. 2–6. *Schulz*, par. i. sect. 2, cap. 4. *Sprengel*, t. i. p. 153 et seq. *Cabanis*, p. 59, 60.)

Although the accounts that have been transmitted to us respecting Æsculapius would lead us to conclude that he was a real personage, who actually possessed a greater degree of medical skill than any of his contemporaries, yet his whole history is so involved in fable and mystery, that it is impossible to obtain any correct idea of the details of his practice. It has been observed above that it was probably, in a great measure, surgical, and even confined almost exclusively to the cure of wounds or recent injuries. The treatment of these may be considered so far judicious as it was simple; it consisted in removing all extraneous bodies, in placing the parts as much as possible in their natural position, in fomentations and ablutions, and in the application of certain vegetables which were supposed to be possessed of balsamic or styptic properties. Wine and other articles of a more stimulating nature were also used, while oleaginous substances were employed nearly with the same intention as in modern times, to defend the part from the air or other external agents, together with bandages and other means of mechanical support. We have no distinct evidence how far internal remedies were administered; for the most part they relied on magical arts and incantations, and although we have reason to believe that certain vegetable products were occasionally employed as internal remedies, we are scarcely able to discover what was the object of the practitioner, and we are frequently unable to ascertain what were the plants that were employed. (*Celsus*, lib. i. præf. *Plinius*, lib. xxix. cap. 1. *Clerc*, part 1, liv. i. ch. 15. *Schulz*, p. i. sect. 2, cap. 4. *Sprengel*, sect. 2, ch. 4, 5. *Cabanis*, ch. 2, § 1.)

But scanty and imperfect as is our knowledge of the state of medicine in the age of Æsculapius, after his death and that of his sons Machaon and Podalirius, we have a long period, extending even to several centuries, during which we have still less information respecting the history and progress of the science. We have not a single improvement of any importance recorded as having taken place during this long interval, nor have we the names of any individuals transmitted to us, who were of sufficient eminence to be distinguished above their contemporaries. We learn that the practice of medicine was entirely confined to the Asclepiades, who were the guardians or superintendents of the temples that were erected in honour of Æsculapius. It may be inferred from the very scanty materials which we possess on the subject, consisting entirely of allusions or indirect accounts, scattered through the works of the older poets and historians, that they sedulously kept up the system of rites and ceremonies, which had been handed down to them from still more ancient practitioners, that they carefully preserved to themselves the sole management of the art over which they presided, and we cannot doubt made use of the influence which they acquired over the minds of their contemporaries for the purposes both of gain and of ambition.† But although we regard the general system of the priests of Æsculapius to be nothing more than a tissue of mystery and delusion, it is very probable that the ample opportunities which they possessed of witnessing the phenomena of disease in all its forms might enable them to obtain much valuable information respecting the nature and tendency of the morbid actions of the body, and of the effects of certain agents upon them. Men possessed of superior talents and sagacity would naturally profit by these advantages, and we accordingly find that some of these temples acquired a high degree of celebrity, in consequence of the supposed skill of the priests that were attached to them. These opportunities of acquiring experience were much facilitated by a practice, which generally prevailed among the patients, whenever they were cured of their diseases, of depositing in the temple a votive tablet, on which was inscribed a narrative of the case, including a statement of the symptoms of the dis-

* *Clerc*, part 1, liv. i. chap. 17. *Sprengel*, t. i. p. 127 et seq. *Goulin*, "Anciens Médecins," in Encyc. Méthod. 'Médecine;" this article may be advantageously consulted on the subject of the Greek and Roman physicians.

† *Lucian*, in his "Philopseudes," gives an account of various medical superstitions which prevailed at a later period, many of which were probably transmitted from the empirics of antiquity. See Tooke's Trans. v. i. p 87 et seq.

ease, and the means adopted for its removal. The temples were thus converted, to a certain extent, into schools of medicine, and as these records were religiously preserved, they became the repositories of much valuable information, which must have gradually led to an improvement in the art. Of the numerous temples that were dedicated to Æsculapius, there were three which acquired peculiar celebrity, those of Cos, of Gnidos, and of Rhodes; we are informed that Hippocrates made great use of these records, and it has even been supposed that one of the treatises which is generally ascribed to him, "Coacæ Prænotiones," was composed from the records which he procured from the temple of Cos.

Some ancient inscriptions have been discovered by the researches of the learned antiquaries of the last century, which would appear to consist of memorials of this kind; and from these specimens we may form some idea of the nature of the information that would be conveyed by them. For the most part they state little more than the name of the disease, together with a very brief account of the means adopted for its relief, which in many cases depended entirely upon certain ceremonies, and in others upon the application of remedies which, we may venture to assert, could have no physical operation. (*Gruter*, Corp. Inscrip. a Grævio, pl. 17 et alibi. *Ackermann*, Opuscula, Diss. 3. sect. 3, by Hundertmark and Carpzov.) Still, however, some experience of the nature and treatment of disease might have been conveyed by their means, and of this we may presume that an individual of a sagacious mind would have availed himself for the improvement of his art.

Among the few circumstances that are transmitted to us respecting the principles and practice of the Asclepiades, we are informed that the priests connected with the two rival establishments of Cos and Gnidos devoted their attention in some measure to different objects; those of the former assumed more of a philosophical cast, attempting to unite reasoning with experience, while the latter attached themselves solely to the observation and collection of mere matters of fact. Hence it would appear that a foundation was thus early laid for the two great sects of the Dogmatists and the Empirics, which long divided the medical world, and the influence of which is, even at this day, not altogether destroyed. We may remark, however, that the philosophy of the school of Cos, if it may be so called, was founded upon such totally incorrect principles, and upon so fallacious a basis, that little immediate benefit was derived from it, and that it was only useful so far as it might lead them to exercise their intellectual powers, and enable them to reason more correctly on medical subjects. By the mode in which Hippocrates speaks of certain practices, such as bleeding and the administration of emetics, purgatives and other analogous medicinal agents, we may infer that they were in common use among his contemporaries, and probably had been so for a long time before him. We may in some instances obtain a knowledge of the vegetable substances that were employed in these early ages, as well as of the individuals who introduced them into practice, by the names which were afterwards imposed upon them by the ancients. It must indeed be obvious that the indication derived from these names is far from being decisive as applied to any particular case, but we derive a general inference from it as to the nature of the articles employed, while they serve to point out the persons who were supposed to have been the most eminent for their skill or their science.

Some centuries had elapsed, during which the practice of medicine continued altogether in the hands of the priesthood, and under their control had remained nearly stationary. It had been exercised, for the most part, for the purpose either of direct emolument, or for the still more selfish purpose of maintaining their influence over the minds of the people, when it began to be cultivated by a different description of persons, much more likely to produce a spirit of improvement, and from whom in reality it derived its first impulse. It was during the sixth century before the Christian æra that the genuine principles of philosophy first made their appearance in Greece, and among the other topics which then became the subject of investigation, the powers and functions of the human body were examined with considerable attention. This led to an inquiry into the nature and cause of diseases, and to the means of their removal; and although a long period elapsed before much actual advance was made in the knowledge of pathology or of the practice of medicine, yet we observe the effect of a more correct mode of reasoning, and may perceive that the strong-holds of mystery and superstition, although not destroyed, were at least in some degree weakened. (*Sprengel*, sect. 3, ch. 1.)

The celebrated name of Pythagoras may be mentioned as the first of this class respecting whom we have any accurate information, and even his history is enveloped in much obscurity. We may, however, conclude with certainty that he devoted the greatest portion of a long life to the pursuit of natural knowledge, that he made many considerable advances in various departments of science, and among others in the knowledge of the structure and actions of the human frame. It has been supposed that he dissected the bodies of animals, and hence acquired a certain acquaintance with anatomy, and that he publicly taught what he knew on this subject to a large assembly of students, who came from all the civilized parts of Greece and Italy to Crotona, where he established his school. We are informed that, for the purpose of acquiring knowledge, he travelled into those countries which, previously to his time, were regarded as the depositaries of knowledge, particularly Egypt, where he is said to have passed no less than twenty-two years, and probably also Chaldæa and some parts of Eastern Asia. From what has been stated above, we may form some conception of the nature of the knowledge that he would obtain from these sources, and we may conclude that he must have been possessed of a very superior mind to have been capable of extricating himself from the trammels of superstition and bigotry in which every thing connected with those countries was involved.*

* *Diogenes Laertius*, lib. viii. cap. 1-50. *Cicero*, de Fin. v. 29. *Valer. Maximus*, viii. 7. *Ælianus*, Hist. Var. iv. 17. *Clemens Alexandrinus*, Stromat. lib. i. p 354-7. *Fabricius*, Bibl. Græc. lib. ii. cap. 12. *Enfield*, vol. i. p. 422 et seq. *Ackermann*, Instit. Per. 2, cap. 4, 5 Opuscula, diss. 4, a Kühn.

We are scarcely able to determine in what degree he directly improved the practice of medicine; it is probable, however, that, as he did not make it his profession, but studied it only in connection with the other branches of natural philosophy, the actual additions which he made to it were not considerable. (*Sprengel*, t. i. p. 337 et seq.) This we may also conclude to have been the case with many of his pupils, who were among the most justly celebrated philosophers of that and the succeeding age. They may all of them be regarded as belonging to the school of Pythagoras, inasmuch as they cultivated natural knowledge by means of observation, and even occasionally of a rude kind of experiment; and although none of them were exclusively devoted to the study of medicine, yet they gradually and indirectly contributed to its advancement, so as to prepare the way for one of those great and commanding geniuses who occasionally make their appearance, and by their intellectual ascendency produce such important revolutions in the world of science: it is unnecessary to state that we here allude to Hippocrates.

During the interval from Pythagoras to Hippocrates there are few names that require any particular notice as improvers of medicine. Democritus (*Clerc*, p. 96–101. *Enfield*, vol. i. p. 422 et seq. *Barchusen*, diss. No. 1. *Sprengel*, t. i. p. 261-6) and Heraclitus (*Clerc*, p. 95, 6. *Sprengel*, t. p. 266–9. *Enfield*, vol. i. p. 436 et seq.) were among the most illustrious followers of Pythagoras, but they became famous rather from the ingenuity with which they supported their peculiar hypotheses than from the additions which they made to actual knowledge. They applied respectively their favourite doctrine of atoms and elements to explain the phenomena of disease, and even the operation of remedies; but, it is unnecessary to say, with little real advantage. The former of these philosophers, however, deserves honourable mention from the attention which he paid to the study of comparative anatomy; and it has been conjectured that he so far rose superior to the prejudices of his age as to venture upon the dissection of the human subject.

The name of Acron is mentioned by Pliny (Lib. xxix. cap. 1) as among the first who attempted, upon any general principles, to apply philosophical reasoning to the science of medicine, but we have scarcely any knowledge of his history or character, nor have we any memorials left of the principles which he adopted. (*Clerc*, part. i. liv. ii. ch. 7.) We may also select the name of Herodicus as having been considered the inventor of what was styled gymnastic medicine, (*Clerc*, part. i. liv. ii. ch. 8. *Mercurialis*, De Arte Gymnastica. *Schulz*, p. 192 et seq. *Barbier*, in Dict. Scien. Méd., art. "Gymnastique." *Ackermann*, per. 2, cap. 6,) which was regarded by the Greeks as a very important branch of the art. Schools for the practice of the gymnastic exercises were established in various parts of Greece, and were placed under the direction and superintendence of persons especially trained for the purpose, who took charge of the health of their pupils, and who appear to have undertaken the treatment both of the accidents which occasionally occurred in their establishments, and also, when necessary, of internal diseases. These gymnasiarchs, as they were styled, must in this way have acquired a certain degree of information respecting the nature of disease, and seem to have been considered as among the most skilful practitioners of the age in which they lived.*

CHAPTER II.—*An account of the opinions and practice of Hippocrates and his contemporaries—Remarks on the history and education of Hippocrates—High estimation in which he was held—Remarks on his character and acquirements—On his works—Account of his principles and doctrines, his physiology, pathology, anatomy, and practice.*

We now enter upon the history of an individual of very distinguished character and acquirements, who was destined to effect a complete revolution in his profession, and to introduce a system which may be considered as having laid a foundation for all its future improvements. The contemporaries and immediate successors of Hippocrates were so sensible of his merit that he acquired from them the title, which he has since retained, of Father of Medicine; and it may be confidently affirmed that the science is more indebted to his genius and ability than to that of any single individual. It is a little remarkable that, notwithstanding the great celebrity which he attained, we have no very correct knowledge of his history, of the mode of his education, or of the means by which he acquired his wonderful pre-eminence. All that we are able to learn on these points with any degree of certainty is, that he was brought up among the Asclepiades, who were attached to the temple of Cos, that he studied medicine under Herodicus, and that he embraced the philosophical hypothesis of Heraclitus; he is also reputed to have been a lineal descendant, in the eighteenth degree, from Æsculapius, and may therefore be supposed to have been devoted to the profession from an early period of life, and must have had access to all the records which were accumulated in the establishment to which he belonged. These circumstances may have had the effect of originally directing his mind to the pursuits in which he afterwards became so eminent; but we must suppose that he possessed from nature a genius singularly adapted to the advancement of medical science, by which he was enabled so far to surpass all those who were placed in situations equally advantageous. We are informed that he spent a considerable portion of his life in travelling through foreign countries, partly for the purpose of obtaining information, and partly from the circumstances of his assistance being required to undertake the cure of persons of rank, to arrest the progress of epidemics, or to check the ravages of endemic diseases. The works that he left behind him are very numerous, and considering their antiquity they may be regarded as in a tolerably perfect state.

Unfortunately, however, to those which appear to have a just claim to be considered as his genuine productions, there are appended a number of

* *Plato*, De Repub. passim. et De Leg. lib. vii. Schulz has judiciously summed up in a series of general propositions the history and progress of medicine up to the period at which we are now arrived; p. 201, 2.

others, which it may be concluded are spurious, either written by his pupils or successors, or fraudently attached to his name in consequence of its great celebrity. Many eminent critics have exercised their ingenuity in endeavouring to separate the genuine from the spurious writings of Hippocrates; and in such estimation was he held, that for many ages a main object with all writers on medical topics was to comment on the works of Hippocrates, to elucidate his principles by subsequent observation, or to support their respective doctrines by his authority. He is mentioned with great respect by Plato, Celsus, and Pliny, and by others among the ancients; Galen speaks of him with a degree of almost enthusiastic admiration, and at the revival of letters the most learned men of the times devoted themselves to the elucidation of his works by glossaries, commentaries, and criticisms of all descriptions. In Italy, Germany, and France, where learning first began to revive, and where the earliest universities were established, we have, among other illustrious names, those of Alpinus, Cornarius, Hollerius, Ballonius, Mercurialis, Fernel, Heurnius, Sennert, Foësius, Riolan, and Duret,* who, however they might differ in their opinions and practice, all coincided in regarding Hippocrates with equal respect, and considered him as having first placed the study of medicine on its correct basis.†

We are hence naturally led to inquire what were the circumstances, in the intellectual or literary character of Hippocrates, which produced this powerful impression, and perhaps we may assign the following as among the most influential. He appears to have had the sagacity to discover the great and fundamental truth, that in medicine, probably even more than in any other science, the basis of all our knowledge is the accurate observation of actual phenomena, and that the correct generalization of these phenomena should be the sole foundation of all our reasoning. Every page of Hippocrates proves that he was not without his speculations and hypotheses, but at the same time we perceive that, for the most part, they were kept in subjection to the result of observation, and that when they appeared to be in opposition to each other, he had the wisdom to prefer the latter. Hence his descriptions of particular diseases, after all the revolutions of customs and habits, both moral and physical, are still found to be correct representations of nature, while his indications of cure, and the treatment derived from them, are generally rational and practicable. When we reflect that at this period anatomy was scarcely practised,‡ that physiology was almost unknown, that the materia medica was nearly confined to vegetable substances, and of these to such as were indigenous to Greece and the neighbouring countries, our admiration of the skill and talents of Hippocrates will be still farther increased, and we are induced to regard him as one of those rare geniuses, who so far outstrip their contemporaries as to form an æra in the history of science.

With respect to the particular improvements which he introduced into the practice of medicine, we may remark that one of the first importance was the narration of individual cases of disease, a plan which may perhaps have been suggested to him by the votive tablets deposited in the temple of Æsculapius, but upon which he so far improved as to be entitled to the merit of an inventor. The second point on which we shall remark, was his method of endeavouring to remove particular symptoms by carefully noticing what have been termed the *juvantia* and the *lædentia*, watching the effect of his applications, and proceeding, by a cautious analogy, from individual facts to more general conclusions, and hence deducing his indications of cure from the operations of remedies, not from any preconceived or abstract principles, which were generally either fallacious or inapplicable. Hence his practice may be characterized as consisting in what has been termed a rational empiricism, where we first ascertain the fact, and afterwards reason upon its consequences.

In speaking of the writings of Hippocrates, it may be proper to remark that the most complete edition of them, in all respects, is that of Foësius, in which every circumstance is attended to that can illustrate them or render them more easily intelligible. He has given a list of all the commentaries and criticisms that had been written upon them, which at the time of his publication, in the year 1595, would of themselves have formed an extensive library. It appears from this list that no less than one hundred and thirty-seven authors had published on the subject of the Aphorisms alone. It was remarked above that many of the writings which are commonly ascribed to Hippocrates, or at least are published in the collection of his works, are supposed not to have been his genuine productions, and hence it has been an object of interest with many eminent critics to distinguish the one from the other. It will not be necessary for us to enter into these discussions in this place; we shall only remark that the number of treatises which are admitted to be certainly genuine is very small compared to the whole number popularly ascribed to him. Of those which are printed in the ordinary editions of his works, which amount to more than sixty, Mercurialis, Haller, Gruner, and other critics conceive that there are a few only which were actually written by Hippocrates, while Ackermann has reduced the number of the genuine works to ten.*

In ascertaining what were the real opinions and practices of Hippocrates, besides the difficulty of discriminating the genuine from the spurious productions, we have a farther difficulty arising from the peculiarity of his style. This is admitted to

* In designating the names of authors who flourished after the revival of letters, it is somewhat difficult to determine, whether we ought to employ their actual or their latinized names; we have adopted the former, where it could be done without ambiguity or the appearance of affectation.

be brief and abrupt, and to be full of ideas compared with the number of words employed to convey them, so that it appeared somewhat obscure even to his contemporaries and immediate successors. Erotianus, who lived in the first century of the Christian era, thought it necessary to write a glossary for the express purpose of elucidating his phrascology; and the immense number of commentaries which have appeared, and which continued to be published until the commencement of the eighteenth century, must be regarded, not only as a tribute to his extraordinary merit, but in some measure as an indirect censure of his style. But after making all due allowance for these peculiarities, after rejecting all the doubtful works and obscure passages, and resting more upon the general scope and tendency of the treatises than on particular words and phrases, we have sufficient evidence left us of the nature of his principles, both as regards theory and practice. Although it is principally in the latter capacity that we are now to regard Hippocrates, yet it will be proper to make a few remarks upon his acquirements in the analogous departments of science.

With respect to his philosophical tenets it appears that the father of medicine must be classed generally among the Pythagoreans, and in the particular sect or school of Heraclitus. The leading doctrine of this philosopher was, that fire is the prime origin of all matter, and that by the collision and peculiar combination of its particles, which are in perpetual motion, the four elements are produced. (*Enfield*, b. 2, c. 14, v. 1. p. 436 et seq.) From this doctrine Hippocrates derived his leading principles of pathology; it lies at the foundation of all his medical hypotheses, and is brought forward in various parts of his works. But although, like all his contemporaries, and indeed nearly all his successors up to the present day, he assumed certain theoretical principles, yet, as we remarked above, he had the extraordinary sagacity to perceive the necessity of detaching medicine from what was then styled philosophy. He professed to examine the phenomena of disease in the first instance, to ascertain what were the natural powers and properties of the animal frame, how far these were affected by external circumstances and by morbid causes, and hence to derive his curative indications and his mode of treatment. It is in the writings of Hippocrates that we observe the first traces of what is properly styled physiology, i. e. an account of the functions and powers of the living body. Although some of his opinions were derived from the school of Pythagoras, and savour of its mysticism and obscurity, yet others appear to have been original, and founded upon a much more correct and philosophical view of the subject. We owe to him the invention of the hypothesis of a principle, to which he gives the appellation of nature (φυσις), which influences all parts of the corporeal frame, superintends and directs its motions, and which is possessed of a kind of intelligence, so as to promote all the actions which are beneficial, and repress those which have an injurious tendency. In addition to this general principle, he conceives of others of a subordinate nature, which he styles powers (δυναμεις), which are more particularly concerned in the action of the various functions of the body. The body itself is supposed to consist of the four elements, combined in different proportions in different individuals, so as to produce an original difference in the constitution of the body, giving rise to the four temperaments. These influence both the intellectual and the corporeal part of our frame, and lay a foundation for disease independent of external circumstances, and cause these circumstances to operate in different modes and in different degrees in different individuals.

One of the leading pathological doctrines of Hippocrates was, that the fluids are the primary seat of disease, a doctrine which, under the denomination of the Humoral Pathology, became the prevailing opinion of all sects and of all theorists, until the commencement of the eighteenth century. The combination of the four elements with the four states or qualities with which they were affected, of hot, cold, moist, and dry, gave rise to the four fluids or humours of the body; blood, phlegm, bile, and black bile, which originally tended to produce the four temperaments, and which in their turn contributed to the excess or defect of each of the humours.

Another of the most important doctrines of Hippocrates is that of crises, or the natural tendency of disease to a cure at certain stated periods, depending upon a natural train of actions, which, when proceeding in their due course, terminate in the removal of the morbid action. These supposed crises were, for the most part, evacuations of various kinds, especially by the bowels or the skin, and hence the regulation of these evacuations led to his most important indications, and became a main part of his practice. There is no subject on which Hippocrates showed more sagacity and accurate observation than in watching the effect of external agents upon the system, such as temperature, the influence of the atmosphere, the effect of particular situations, of the seasons, and other analogous circumstances. In most of these cases the causes were obscure, and he frequently erred in his attempts to explain them; but his observations were correct, and contributed materially to the success of his practice.

The extent of knowledge which Hippocrates possessed on the subject of anatomy has given rise to much learned discussion. While his admirers were unwilling to admit that he was deficient in any of the departments of medical science, and attempted to prove that he had acquired a correct knowledge of the structure of the body, it has been contended, on the other hand, that on this point his information was very imperfect. This may be readily supposed to be the case from the abhorrence with which the dissection of the human subject was regarded at that period, and from the little attention which was paid even to comparative anatomy. There are likewise other considerations of an especial nature, which lead us to conclude that he had little knowledge of the internal structure of the body, or of the relation of its different parts to each other. Notwithstanding, therefore, the claim which has been set up for Hippocrates, by some of his devoted advocates, to a knowledge of the circulation of the blood, and other claims equally extravagant and unfounded, we may conclude, with the learned and candid Le

Clerc, that the knowledge which Hippocrates possessed of anatomy was little if at all superior to that of his contemporaries. (*Clerc*, part 1, liv. liv. iii. ch. 3. *Shulz*, per. 1, sec. 3, cap. 2, § 1-8. *Sprengel*, t. 1. p. 302 et seq. *Gruner*, Analecta, No. 2. *Lauth*, liv. iii. passim.)

After these brief observations on the theoretical doctrines of Hippocrates, and of the knowledge which he possessed in the various departments of medical science, we must conclude this chapter with a somewhat more minute account of his practice. Although he has published no regular treatise on practical medicine, nor laid down any specific rules on this subject, he has given us in several parts of his works a minute detail of his treatment of various diseases, so that we are enabled to ascertain, with considerable minuteness, the general principles on which he acted, as well as the mode in which he applied them. The great principle which directed all his indications was the supposed operation of "nature," to which we have referred above, in superintending and regulating all the actions of the system. The chief business of the physician is to watch these operations, to promote or suppress them according to circumstances, and perhaps in some rare cases to attempt to counteract them. The tendency of this mode of practice would be to produce extreme caution, or rather inertness, on the part of the practitioner, and we accordingly find that Hippocrates seldom attempted to cut short any morbid action, or to remove it by any decisive or vigorous treatment. Considering the state of knowledge on all subjects when he lived, it must be admitted that this plan of proceeding was much more salutary than the opposite extreme, and that it had likewise the good effect of enabling the practitioner to make himself better acquainted with the phenomena of disease, and by observing the unaided efforts of nature, to form his indications with more correctness, and to determine to what object he ought more particularly to direct his attention. It has been remarked that a man who is possessed of an acute and penetrating genius, however strongly he may be attached to a favourite hypothesis, contrives to adapt it to the information which he acquires, and this was in some measure the case with Hippocrates. For, notwithstanding the grand principle of the all-sufficient and unerring superintendence of nature, we have another general principle brought into view, which appears altogether of an opposite tendency, viz. that a disease is to be cured by inducing a contrary state of the system, or a contrary action in the morbid part. Thus, repletion is to be relieved by evacuation, and the effect of excessive evacuation to be removed by inducing repletion; the excess or defect of any of the humours or qualities is to be relieved by the employment of such means as may augment or diminish the contrary humour or quality. Perhaps it may be said that in these cases the practitioner is in fact only anticipating the operation of nature, or producing that change which would naturally ensue were there not some unusual counteracting cause which prevented or repressed it. But it is of comparatively little consequence in what way he reconciled this apparent discordance, we have every reason to feel assured that this mode of treatment is frequently correct, and Hippocrates evinces the superiority of his genius by not suffering his judgment to be warped even by the influence of a favourite hypothesis.

A third principle which very materially affected the practice of Hippocrates was the doctrine of critical evacuations, to which we have alluded before. As diseases were supposed to originate in the prevalence of some morbid humour, so when they are suffered to run their course without interruption they are relieved by the discharge of the humour, and consequently the promotion of this discharge becomes an important indication which it is often easy to accomplish, and which proves very effectual. Hence an important part of his practice consisted in the employment of evacuations of various kinds, and especially of purgatives, of which he used a great variety and administered them with great freedom. This, indeed, was the only part of his practice which can be considered as decidedly active, but even here we do not perceive that he transgressed the limits of prudence, while in the selection of the remedy and its adaptation to each particular case, he manifested considerable judgment and sagacity. With the same intention he prescribed diuretics and sudorifics; he drew blood both by the lancet and the scarificator; he applied the cupping-glasses; he administered injections and inserted issues. He made very frequent use of external applications, such as ointments, plaisters, liniments, &c., and was familiarly acquainted with the effects of external temperature. His materia medica was tolerably copious, and embraced many articles which still retain their place in our pharmacopœias. They were almost exclusively of vegetable origin, for the preparations which depend on chemical processes, such as metallic salts and oxides, the strong acids, with the spirituous compounds, were then totally unknown.

One important part of medical practice to which Hippocrates paid particular attention was the regulation of the diet; in this he displayed much sagacity and discernment, as well as on all points connected with the management of his patients, with regard both to the cure and prevention of disease. He appears to have been the first who noticed what has been called the epidemic constitution of the seasons, that inexplicable condition of the atmosphere, or of those influences to which the body is exposed, which appears to render it more or less obnoxious to certain morbid causes, and even to generate these causes at certain periods, without our being able to refer their production to any more general principle.

The tendency of the practice of Hippocrates to allow the operations of the system to pursue their course without interruption, united with his natural sagacity, enabled him to acquire great skill in prognostics, so that there is no part of his writings which exhibits more distinctive marks of a superior understanding than those in which he treats on this topic. Upon a review of the character and writings of this celebrated individual, we conceive that we are warranted in the conclusion, that while there are few persons of any age or nation who attained to greater distinction among their contemporaries, or whose memory has been more cherished by posterity, there was perhaps no

one whose fame was more merited or established upon a firmer foundation.*

CHAP. III.—*History of Medicine from the time of Hippocrates until its introduction into Rome—Establishment of the Dogmatic sect—Plato—Aristotle—School of Alexandria—Erasistratus—Herophilus—Division of Medicine into different departments—Into the Dogmatic and Empiric sects—Their general principles.*

We have not much to add respecting the state of medicine during the period which immediately succeeded to the death of Hippocrates. The advance which he made in the science, and the improvement which he introduced into the practice, were so considerable, that no one appeared for some centuries who was able to proceed, at least in any considerable degree, beyond the point of perfection to which it had been brought by the great father of medicine. In conformity with the custom of the times, Hippocrates transmitted his profession to his sons Thessalus and Draco, and we are informed that it continued to descend in the direct hereditary line for several successive generations. Polybus, his son-in-law, is singled out as having fully maintained the credit of his illustrious relative, and it is even said that many of the writings usually ascribed to Hippocrates are in reality the production of Polybus. (*Clerc*, part i. liv. iv. ch. 1.)

The only other names which we meet with in the annals of medicine among the Asclepiades, that are in any considerable degree distinguished, are, Diocles of Carystus, and Praxagoras of Cos. The former of these obtained a high reputation for his learning and practical skill: he appears to have adopted for the most part the opinions and practice of Hippocrates. (*Clerc*, part i. liv. iv. ch. 5. *Schulz*, p. ii. cap. 1, § 10–22. *Sprengel*, t. i. p. 366–2.) Of the latter, although he is enumerated among the successful improvers of the art, we have only very imperfect and unsatisfactory accounts. We are, indeed, informed that he paid great attention to anatomy, that he particularly noticed the state of the pulse, and derived many of his indications from this source; but we have little except the general fact of the estimation in which his name was held by his contemporaries, which can enable us to form an estimate of his merit. (*Clerc*, part i. liv. iv. ch. 6. *Schulz*, p. ii. cap. 1, § 23–8. *Sprengel*, t. i. p. 372–4.) The name of Chrysippus may be noticed in this place as one who appears to have been a kind of irregular practitioner, as we should style him, who did not belong to the family of the Asclepiades, and was principally remarkable for the innovations which he introduced into practice.† But like too many of those whose fame is principally founded on the novelty of their opinions, we do not find much to commend in them. We are told that he did not allow, in any case, of bleeding, and that he discountenanced the employment of all active purgatives; and, in short, that he rejected many of the most powerful and effective agents in the treatment of disease. (*Clerc*, part ii. liv. i. ch. 1. *Schulz*, p. i. sect. 3, ch. 5, 6. *Sprengel*, t. i. p. 365.)

Draco and Thessalus, in conjunction with their relative Polybus, are generally regarded as the founders of what has been considered as the first medical sect or school which was established upon rational principles. It obtained the name of the Hippocratean, or more generally the Dogmatic school or sect, because it professed to set out with certain theoretical principles which were derived from the generalization of facts and observations, and to make these principles the basis of practice.

Although we can have no hesitation in pronouncing this to be the correct and legitimate method of pursuing the study of medicine, yet it must be acknowledged at the same time that it is a method which, if not carefully watched and strictly guarded by prudence and sagacity, is exposed to the greatest danger of being corrupted by ignorance and presumption. Hence we may easily conceive that it would be liable to fall into the grossest errors, and to lie open to the most serious imputations, and that a fair plea would always be found for exclaiming against the introduction of what is termed theory into the practice of medicine. This abuse of the principles of the Dogmatists gave rise to the rival sect of the Empirics, who, perceiving the false reasoning of the former, and the injudicious practice consequent upon it, professed to be guided altogether by experience, and to discard all theory. For many centuries these two sects divided the medical world, and even at this day, after all the revolutions of opinion and the improvements of science, we may observe very distinct traces of their influence. It was not, however, until a considerably later period that the Empirics formed themselves into a distinct sect and became the declared opposers of the Dogmatists. (*Sprengel*, sect. 4, ch. 1.)

Besides the individuals who belonged to the family of the Aselepiades, and who made medicine their particular profession or pursuit, most of the philosophers of Greece bestowed a certain degree of attention upon this science; for it appears that among the ancients, a knowledge of medicine was regarded as one of the branches of philosophy which was included in a course of general education. The only two, however, of the Grecian philosophers whom it will be necessary to mention on the present occasion, are Plato and Aristotle, who, although they did not compose any treatises on medicine strictly so called, make frequent allusions to it in various parts of their writings. The former of these authors, in his dialogue styled Timæus, and in his treatise de Republica, has entered into various physiological discussions respecting the functions of the body, and the supposed effect of their derangement in producing the morbid conditions of the system, and has offered various incidental observations on the practice of his contemporaries. But it does not appear that either the theory or the practice of medicine received any improvement from this philosopher. He made little or no addition to the

† Pliny remarks of him, "Horum (referring to previous physicians) placita Chrysippus ingenti garrulitate mutavit." Nat. Hist. lib. xxix. cap. 1.

actual stock of our knowledge in any branch of natural science, while his peculiar genius rather led him to the formation of hypotheses and speculations derived from fanciful analogies, tinged with that air of mystery which pervades most of his writings. (*Clerc*, part i. liv. iv. ch. 3. *Stanley's* Hist. of Phil. part v. ch. 22, p. 79 et alibi. *Sprengel*, t. i. p. 337 et seq.)

Both the original turn of mind and the pursuits of Aristotle were much better adapted to improve the science of medicine than those of Plato. He made very great advances in the knowledge of nature; he was peculiarly well situated for the acquisition of new information on all subjects connected with natural history, and he diligently availed himself of his advantages. He was the first writer who published any regular treatises on comparative anatomy and physiology, and his works on these subjects may be still read with much interest, after all the additions which have been made to them by the labours of the moderns. (*Douglas*, Bibliogr. Anat. p. 9–11.) But, notwithstanding all these favourable circumstances, it may be questioned whether the influence of Aristotle has not been ultimately somewhat unfavourable to the progress of knowledge. With his valuable facts and observations he mixed up a large portion of recondite and refined speculation, so that it is frequently not easy to separate the one from the other; and so great was the ascendency which his genius acquired over the minds of men for many centuries after his death, that all his opinions, the most unfounded as well as the most philosophical, were indiscriminately received as established truths, which no one ventured to oppose or to controvert. (*Clerc*, part i. liv. ii. ch. 4. *Schulz*, p. ii. cap. 1, § 2 et seq. *Stanley*, part vi. passim. *Sprengel*, sect. 4, cap. 2.)

The next circumstance which we are called upon to notice in the history of medicine, is the establishment of the school of Alexandria. This was effected by the munificence of the Ptolemies, who, about three hundred years before the Christian era, laid the foundation of the celebrated Alexandrian library and of the school of philosophy, which is graced by so many illustrious names. The science of medicine was cultivated in this school with peculiar assiduity, and we owe some very essential improvements to its professors. Among the most famous of these are Erasistratus and Herophilus. We have not much accurate information respecting the personal history of these two individuals, nor have any of their works been transmitted to us; but we have a detailed account of their opinions and practice, given us by Galen, Cœlius Aurelianus, and others, so as to enable us to form a tolerably correct estimate of their merits. They are particularly mentioned as being the first who dissected the human subject, for which purpose the bodies of criminals were allotted to them by the government; and it appears that they amply profited by the advantage which was thus given them, so as very considerably to advance our knowledge of the structure of the body, especially by pointing out those circumstances in which the human subject differed from that of the animals who most nearly resembled it, and in correcting the errors on this point into which their predecessors had fallen. Nearly every part of the great system of which the body is composed, profited by their labours; they ascertained, with much more correctness than it had been previously done, the structure of the heart and the great vessels, and of the brain and nerves, and they even seem to have had some imperfect knowledge of the absorbents. We are informed that Erasistratus was the pupil of Chrysippus, and that he imbibed from him his prejudice against bleeding, and against the use of active remedies, trusting more to the operations of diet or the natural efforts of the system: hence we are to regard him as having improved the practice of medicine only indirectly, by the addition which he made to our knowledge of anatomy. (*Clerc*, part ii. liv. i. ch. 2–4. *Schulz*, p. ii. cap. 3, § 35–66. *Sprengel*, t. i. p. 439 et seq. *Lauth*, p. 140, 1.) The anatomical fame of Herophilus is so intimately blended with that of Erasistratus, that we are unable to assign to each his respective share of merit; but it would appear that the former was more correct and more skilful in the practical department. Of this we have one proof in the fact, which is stated by Galen, that Herophilus was one of the first who paid very minute attention to the varieties of the pulse; and his name is handed down to us by the ancients as entitled to the highest respect, both from his character and his acquirements.*

An important circumstance in the history of medicine, and more especially in that department to which our attention is particularly directed, occurred soon after the establishment of the Alexandrian school, viz. the division into distinct professions, which were exercised by different individuals. Previously to this period, the practice of what is more especially styled medicine and of surgery was exercised by the same person; the ἰατρος of the Greeks corresponding nearly to what we should now term the general practitioner. But about this time the separation into the departments of dietetics, pharmacy, and surgery commenced, and was gradually admitted into all succeeding schools or sects. The terms did not, however, possess precisely the same signification as in modern times. Dietetics comprehended not the regulation of the diet alone, but every circumstance connected with the general health or management of the patient, and corresponded very nearly to the "medicus," or physician of modern times. The second included not merely the department of the apothecary or the compounder of drugs, but the performance of many of the operations of surgery; while to the third was allotted the treatment of surgical diseases, many of the operations, however, being committed to the professors of the second branch. That this separation eventually tended to the improvement of the respective branches of the profession will scarcely be doubted, although it must at the same time be acknowledged that many of the distinctions which were introduced were frivolous and invidious, and are now rapidly yielding to the superior intelligence of modern times. (*Celsus*, lib. i. præf. *Schulz*, p. ii. cap. 5. *Clerc*,

* *Clerc*, part ii. liv. i. ch. 6. *Schulz*, p. ii. cap. 3, sec. 2–34. *Sprengel*, t. i. p. 43 et seq. *Lauth*, p. 139, 140.—For an account of the Alexandrian school generally, see *Sprengel*, sect. 4, ch. 3; and *Lauth*, liv. iv.

part i. liv. ii. ch. 9. *Eloy*, "Partage de la Médecine.")

It was about this period, i. e. shortly after the establishment of the Alexandrian school, that the great schism to which we have so often alluded took place. It was occasioned by the formation of the rival sects of the Dogmatists and the Empirics. Neither of these terms, in the first instance, bore exactly the same meaning which they convey to a modern ear. The controversy really consisted in the question, how far are we to suffer theory to influence our practice. While the Dogmatists, or, as they were sometimes styled, the Rationalists, asserted that before attempting to treat any disease, we ought to make ourselves fully acquainted with the nature and functions of the part which is affected, or rather of the body generally, with the operation of medical agents upon it, and with the changes which it undergoes when under the operation of any morbid cause; the Empiric, on the contrary, contended that this knowledge is impossible to be obtained, and, if possible, is not necessary;—that the minute and internal changes of the system and of its different parts are beyond the reach of our most acute observation, that it is alone essential to watch the phenomena of disease, and to discover what remedies are best fitted to relieve the morbid symptoms; that our sole guide must be experience; and that, if we step beyond this, either as derived from our own experience or observation, or that of others on whose testimony we can rely, we are always liable to fall into dangerous and often fatal errors. We may remark that this controversy, like so many others which have occupied the attention of mankind for a succession of ages, is partly verbal, and in so far as it is not verbal, that it is a question of degree. The boldest Dogmatist professes to build his theory upon facts, and the strictest Empiric cannot combine his facts without some aid from theory. The uniform experience of all the schools and sects from the days of Hippocrates to the present time, demonstrates that the undue extension of either of these systems is injurious, that they both originate from a partial view of the subject, and may generally be traced to some defect either in the acquired information or natural disposition of the practitioner. The controversy, however, forms so prominent a feature in the history of medicine, that it will be necessary to advert to it very frequently in the following pages; and we shall find that in estimating the value of the various opinions or modes of practice which will successively pass under our review, it will in most cases be necessary to inquire from which of these sects they emanated.*

Respecting the individuals to whom the origin of these sects should be referred, there is some degree of obscurity: the Dogmatists generally claim Hippocrates for their founder, and it is certain that he investigated with great care the functions of the animal body, the action of morbid causes upon it, and the operation of remedies, or, as we should style them, the general principles of pathology and therapeutics. But while, in this respect, he acted upon the principles of the Dogmatists, he was no less remarkable for the accuracy with which he observed the phenomena of disease, and the actual operation of remedies upon individual cases, or even upon particular symptoms; and it may be affirmed that, in most instances, when his preconceived hypotheses seemed to be in contradiction to the results of his experience, he wisely followed the latter. We may, however, easily imagine that his successors, not being possessed of his sagacity and industry, would prefer the easiest method of indiscriminately adopting all his principles and speculations, to the more arduous task of correcting or extending them by their own observation, and that they would in this way bring all theoretical reasoning into disrepute. It is more probable that this feeling would be gradually induced in the minds of practitioners, than that it would be at once announced by any single individual; and as a matter of historical fact, the ancients themselves were divided in their opinion as to the person to whom they should ascribe the origin of the Empirical sect. Pliny attributes it to Acron, a physician of Sicily, (Lib. xxix. cap. 1,) who was contemporary, if not prior to Hippocrates; while Celsus states that Serapion of Alexandria, who was said to be a pupil of Herophilus, was the first who distinctly professed the opinion that theory is to be totally discarded in medicine, and that direct experience should be our sole guide. (In præf. sub initio.) We have little correct information respecting either the history or the practice of Serapion; none of his writings have been transmitted to us, but from the scattered notices which we meet with concerning him, dispersed through the works of the ancients, it may be conjectured that he was a man of considerable acuteness and sagacity, and that he generally adopted the practice of Hippocrates and his school, although he discarded their theory. (*Schulz*, per. ii. cap. iv. § 8. et seq.)

All the medical men of the period at which we are now arrived, and for some centuries subsequent to it, were attached to one or other of these rival sects, and, it would appear, in nearly an equal proportion. Unfortunately, however, for the Empirics, it has happened that all their writings have perished, so that we are obliged to form our opinion of their merits principally from the representation of their antagonists. There is, indeed, one happy exception in the works of Celsus, who, in the commencement of his treatise, has given an account of the leading opinions of the two opposing sects in so candid and judicious a manner, as almost to supersede any more elaborate discussion. It has been thought by many that the view which Celsus gives of the controversy is too favourable to the Empirics; and we admit that we can scarcely read his account without being impressed with the opinion, that he advocates their side of the question. Yet the conclusion which he draws is perfectly candid, and is, indeed, not very remote from what the most enlightened practitioner would form at the present day;—that the perfect rule of practice is derived from a due combination of reason and experience; that without experience all preconceived theory would be vain and useless; and that by simple experience, without any attempt at generalization, we should frequently fall into gross errors, and be unable to profit even by

* For an elegant summary of the arguments employed in this controversy, the reader is referred to *Percival's* Essays, Nos. 1 and 2.

the very experience which is so much extolled. And, indeed, whatever may have been the professed plan of the supporters of the two sects, we shall always find that the practice of the most eminent of either party actually proceeded upon a judicious combination of the two systems; and we are now persuaded that it is upon such a combination that all further improvements of the science and practice of medicine must essentially depend.*

CHAPTER IV. — *On the state of Medicine among the Romans from its first introduction into Rome until the time of Galen—Roman superstitions—Archagathus—Cato—Asclepiades—Themison—Origin of the Methodic sect — Thessalus — Saranus — C. Aurelianus — Doctrines of the Methodics—Pneumatics and Eclectics—Aretæus—Archigenes—Celsus, his doctrines and practice—Condition of physicians in Rome—Pliny—Dioscorides.*†

For some centuries the school of Alexandria produced a succession of learned men, not only in medicine but in the other sciences, and contributed to the advancement of knowledge, or at least prevented the decay into which it was in danger of falling after the decline of the Grecian literature. It was during this period that the foundation was laid of the future grandeur of the Roman empire; but from the attention of this people being almost exclusively directed to warlike affairs, and perhaps also from other causes, science of all kinds, and medicine among the rest, was for a long time almost totally neglected. Rome had extended her empire far beyond the limits of Italy, and had subdued most of her rivals, before she condescended even to tolerate the pursuit of the arts and sciences. We are expressly told by Pliny, that for six hundred years she was without physicians. We cannot conceive it possible that during this long period no attempts were made to remove diseases; we can only understand by it that there were no individuals eminent for their knowledge or skill who were engaged in the profession, or perhaps that it was scarcely regarded as the object of distinct pursuit, or that individuals were not especially trained to the exercise of it. We have, indeed, abundant evidence of two circumstances; that in this, as in every other subject connected with the arts of life, the Romans servilely copied from the Greeks,‡ and that, as far as their medicine was concerned, wherever they deviated from them it was for the purpose of adopting various superstitious rites and ceremonies, indicating the most profound ignorance and the grossest superstition. Numerous instances of this kind are incidentally mentioned by Livy; and although he wrote in the refined age and splendid court of Augustus, they are introduced in the thread of his narrative as actual transactions, without any observation indicative of his disbelief of their efficacy.§ One of these is the account which he gives of the introduction of the worship of Æsculapius into Rome. In consequence of a fatal epidemic, the senate had recourse to the usual expedient of consulting the Sibylline books, where it was found to be enjoined upon them to transfer the worship of the god from Greece to their city. A formal deputation was accordingly despatched for the purpose, by whom the deity, unwilling to leave his native place, was seized by a stratagem, and was conveyed under the form of a serpent into Italy. He was received by the people of Rome with unbounded transport; a temple was erected to him on an island in the Tiber; the usual appendages of priests, with all their ceremonies, were appointed; and the plague was of course suspended.‖

Pliny further informs us that medicine was introduced into Rome at a later period than most of the other arts and sciences; that the practice of it had even been expressly prohibited by the citizens, and its professors banished. The account which he gives of so singular an occurrence is, that about two hundred years before Christ, Archagathus, a Peloponnesian, settled at Rome as a practitioner of medicine, and, as it may be inferred, was the first person who made it a distinct profession. He was received in the first instance with great respect, and was even maintained at the public expense; but his practice was observed to be so severe and unsuccessful, that he soon excited the dislike of the people at large, and produced a complete disgust to the profession generally, which led to the transaction mentioned above.¶ His practice seems to have been almost exclusively surgical, and to have consisted, in a great measure, in the use of the knife and of powerful caustic applications. We hear little more of the state of medicine in Rome for the next century; but from certain incidental observations we may infer that it remained principally in the hands of the priests, and consisted as before in superstitious rites and ceremonies. It appears, indeed, that the few individuals who devoted themselves to the cultivation of natural science, among other subjects directed their attention to medicine; and it is particularly stated that Cato introduced various articles into the materia medica, and wrote several treatises on medical topics. We are not able to form any just conception of their merit from the account which is given of them; but it is worthy of remark that he was a professed opponent to Grecian literature in general, and we may therefore conclude, would not avail himself of the improvements that had been made by the Greek physicians.**

* *Galen*, de Subfigurat. Empir. et alibi. *Celsus*, in Præf. *Barchusen*, Diss. nos. 10 & 13. *Clerc*, pars ii. liv. ii. *Shulz*, per. ii. cap. iv. *Sprengel*, sect. 4, ch. 1, 4. *Ackermann*, p. iii. cap 10–13.

† For a concise, and at the same time a comprehensive view of this period of the history of medicine, the reader is referred to the fifth section of Blumenbach's Introduction. We may further remark that this work may be consulted with advantage, in connection with almost all the names that pass in succession under our review.

‡ *Suetonius*, de Grammat. sub initio; the fact is admitted by Cicero and by Pliny, and is frequently alluded to in various parts of their writings.

§ The following references may be selected among many others of a similar kind:—Book i. ch. 31, Tullus consults the Sibylline books in order to stop the plague; —iv. 25, for the same purpose a temple was erected to Apollo;—v. 13, the books were again consulted;—vii. 2, a lectisternium was ordered for the same purpose, and afterwards the public games;—vii. 3, the plague was stopped by the dictator driving a nail.

¶ Lib. xxix. cap. 1.

** *Clerc*, pars ii. liv. iii. ch. 1. *Schulz*, p. ii. cap. 6. *Ackermann*, p. iv. cap. 15.

We may presume that the prejudice which was excited against Archagathus would be gradually allayed, and that the improvement of the Romans in intellectual cultivation, although not considerable, would be at least sufficient to make them sensible of the necessity of attempting something beyond the mere power of charms and incantations for the removal of disease. Accordingly, about a century before the Christian æra, we find that another individual had acquired a very considerable degree of popularity at Rome which he maintained through life, and in a certain degree transmitted to his successors,—Asclepiades of Bythinia. It is said that he first came to Rome as a teacher of rhetoric, and that it was in consequence of his not being successful in this profession, that he turned his attention to the study of medicine. From what we learn of his history and of his practice, it would appear that he may be fairly characterized as a man of natural talents, acquainted with human nature, or rather with human weakness, and possessed of considerable shrewdness and address, but with little science or professional skill. He began upon the plan which is so generally found successful by those who are conscious of their own ignorance, by vilifying the principles and practice of his predecessors, and by asserting that he had discovered a more compendious and effective mode of treating diseases than had been before known to the world. As he was ignorant of anatomy and pathology, he decried the labours of those who sought to investigate the structure of the body, or to watch the phenomena of disease, and he is said to have directed his attacks more particularly against the writings of Hippocrates. It appears, however, that he had the discretion to refrain from the use of very active and powerful remedies, and to trust principally to the efficacy of diet, exercise, bathing, and other circumstances of this nature. A part of the great popularity which he enjoyed depended upon his prescribing the liberal use of wine to his patients, and upon his attending in all cases, with great assiduity, not only to every thing which contributed to their comfort, but that he flattered their prejudices and indulged their inclinations. By the due application of these means, and from the state of the people among whom he practised, we may, without much difficulty, account for the great eminence to which he arrived, and we cannot fail to recognise in Asclepiades the prototype of more than one popular physician of modern times.

Justice, however, obliges us to admit that he seems to have been possessed of a considerable share of acuteness and discernment, which on some occasions he employed with advantage. It is said that to him we are indebted, in the first instance, for the arrangement of diseases into the two great classes of acute and chronic, a division which has a real foundation in nature, and which still forms an important feature in the most improved modern nosology. In his philosophical principles Asclepiades is said to have been a follower of Epicurus, and to have adopted his doctrine of atoms and pores, on which he attempted to build a new theory of disease, by supposing that all morbid action might be reduced into obstruction of the pores and irregular distribution of the atoms. This theory he accommodated to his division of diseases, the acute being supposed to depend essentially upon a constriction of the pores, or an obstruction of them by a superfluity of atoms; the chronic, upon a relaxation of the pores, or a deficiency of the atoms.*

Asclepiades was succeeded in his professional reputation by his pupil Themison of Laodicea, who had the honour of founding a new sect in medicine, which for some time almost eclipsed the former rivals; this was the Methodic sect. The great object of Themison seems to have been to adopt a middle course between the Dogmatists and the Empirics, and to take advantage of the excellencies of each of them. He was, however, strongly impressed with the great principle of Asclepiades, the importance of reducing the science to a few general laws, which by their simplicity might be universally intelligible and of easy application. He therefore rejected all the abstruse and recondite speculations of the Dogmatists, and substituted in their place a few positions derived from the tenets of his master, and founded upon the Epicurean doctrines. He remarks that it is an essential part of the business of the practitioner to make himself acquainted with the nature of the human frame, with its laws while in the state of health, and with the changes which they experience from disease. All these he referred to the respective states of constriction and relaxation, and to the undue preponderance of one of them over the other. To these two, however, he added a third, or mixed state as he styled it, the nature of which is not very easy to understand; while by classing all medical agents under the two great divisions of astringents and relaxants, we learn how to apply the appropriate remedy for every disease.

Themison's doctrine must be regarded as a refinement, and certainly an improvement of that of Asclepiades; for although we have the states of constriction and relaxation professedly copied from his master, it is disencumbered of the more objectionable speculation of the atoms and pores. The theory of the Methodics contemplates the solids as the seat and cause of disease, in which respect it is directly opposed to that of Hippocrates, who traced the primary cause of disease to an affection of the fluids, giving rise to what has been termed the Humoral Pathology. The humoral pathology was zealously defended by Galen, and was universally adopted by his successors until the seventeenth century, when the opposite doctrine of solidism was revived, and has been gaining ground until the present day. It has been justly objected to Themison's theory, that even if we admit the correctness of his views respecting the states of constriction and relaxation of the system, there is a palpable absurdity in supposing that they can be coexistent in what he terms his middle state, as they are directly opposed to each other.

There is no work of Themison's extant, but we have an ample account of his practice in the writings of Cælius Aurelianus, who was a zealous

* *Plinius*, passim. *Celsus*, ubi supra et alibi. *Clerc*, pars ii. liv. iii. ch. 4–9. *Sprengel*, sect. 5, ch. 1. *Cabanis*, ch. 2, sect. 5. *Goulin*, Encyc. Méth., "Medecine Asclepiade." *Chaussier et Adelon*, in Biog. Univ., "Asclepiade."

defender of the tenets of the Methodic sect. They appear to have been diligent in the observation of the phenomena of disease, and sagacious in their employment of remedies; they seem, indeed, to have sustained their character of keeping a middle course between the Dogmatists and Empirics, avoiding the extremes of either, and combining the more useful parts of each system in a greater degree than had been done by their predecessors. (*Celsus*, in præf. *Clerc*, p. ii. liv. iv. sect. 1, ch. 1. *Barchusen*, Diss. 11. *Sprengel*, t. ii. p. 20–3. *Ackermann*, per. iv. ch. 17.)

For some time after the death of Themison, the opinions of the Methodics were generally adopted in Rome, and almost superseded those of the professed Dogmatists and Empirics, so that we shall have little to detain us in our progress, except to notice certain individuals who became remarkable from their personal history or character, or from some peculiarity in their opinions or practice. The first of this description in point of time is Thessalus, who lived about half a century after Themison, and who ranks as one of his followers. He was, however, an individual very different, both in character and in acquirements, from his master. He is stated to have been of mean birth and of defective education, but by cunning and artifice to have acquired great wealth and a high reputation. He began his career, in the usual mode of ignorance and self-sufficiency, by endeavouring to throw contempt on all his predecessors and contemporaries, by pretending to expose their errors, and by claiming to himself the discovery of a new theory of medicine, which should lead to more correct practice, and should supersede all farther attempts of the kind; in fine, he assumed to himself the pompous title of the conqueror of physicians (ιατρονικες).*

We shall not have occasion to dwell long upon one who is so unworthy of a place in the records of science; it is only necessary to remark concerning him, that he appears to have united the speculations of Asclepiades with those of Themison, and to have admitted the atoms and pores of the one, with the constriction and relaxation of the other. The only addition which Thessalus made to medical theory which deserves notice, is the introduction of what he terms metasyncrasis, or the method of producing an entire change in the state of the body. This he opposed to the practice of Hippocrates, who professed to watch over and regulate the actions of the system, as well to that of the Empirics, whose aim was to correct specific morbid actions, or to remove particular morbid symptoms. The term, as conveying a conceivable, if not an actual occurrence, was not without its value, and was generally adopted by medical writers; and even in the present day the principle implied in it serves as the foundation for some of our most important indications. (*Clerc*, p. ii. liv. iv. sect. 1, ch. 2, 3. *Sprengel*, t. ii. p. 28–31.)

The name of Soranus next occurs among the celebrated Roman practitioners. There is, indeed, some reason for supposing that there were no less than three physicians of this name, but the one who is most eminent appears to have been a native of Ephesus, to have studied at Alexandria, and finally to have settled in Rome. He was a strict Methodic, and is said to have been highly respected for his character and talents. His writings have not been transmitted to us, but probably the most valuable information which they contain is handed down to us by C. Aurelianus, whose work, if not, as some have supposed, a translation of Soranus's treatise, proceeds upon the same principles, and inculcates the same practice. (*Clerc*, p. ii. liv. iv. sect. 1, ch. 4. *Sprengel*, t. ii. p. 33–35.)

There is considerable uncertainty respecting both the age and the country of C. Aurelianus. Some writers place him as early as the first century of the Christian æra, while others endeavour to prove that he was at least a century later. This opinion is principally founded upon the circumstance of his not mentioning or being mentioned by Galen, indicating that they were contemporaries or rivals. Numidia has been generally assigned as his native country, but perhaps without any direct evidence; it may, however, be concluded from the imperfection of his style and the incorrectness of some of the terms which he employs, that he was not a native either of Greece or of Italy. But whatever doubts may attach to his personal history, and whatever defects exist in his writings, they afford us much valuable information respecting the state of medical science. He was a professed and zealous Methodic, and it is principally from his work that we are able to obtain a correct view of the principles and practice of this sect. In his descriptions of the phenomena of disease, he displays considerable accuracy of observation and diagnostic sagacity; and he describes some diseases which are not to be met with in any other ancient author. He gives us a very ample and minute detail of the practice which was adopted both by himself and his contemporaries; and it must be acknowledged that on these points his remarks display a competent knowledge of his subject, united to a clear and comprehensive judgment.

He divides diseases into the two great classes of acute and chronic, nearly corresponding to diseases of constriction and of relaxation, and upon these supposed states he founds his primary indications; but with respect to the intimate nature of these states of the system, as well as of all hidden or recondite causes generally, he thinks it unnecessary to inquire, provided we can recognise their existence, and can discover the means of removing them. Hence his writings are less theoretical and more decidedly practical than those of any other author of antiquity; and they consequently contributed more to the advancement of the knowledge and actual treatment of disease than any that had preceded them. They contributed in an especial manner to perfect the knowledge of therapeutics, by ascertaining with precision the proper indications of cure with the means best adapted for fulfilling them. The great defect of C. Aurelianus, a defect which was inherent in the sect to which he belonged, was that of placing too much dependence upon the two-fold division

* *Plinius*, lib. xxvii. cap. 1.—We have an amusing, and probably a correct account, given us by Lucian, of the successful knavery practised by an impostor of his age, named Alexander; see Tooke's Trans., vi. p. 630 et seq. He appears to have been a worthy successor of Thessalus, so far as respects his arrogance and presumption.

of diseases, and not sufficiently attending to the minute shades by which they gradually run into each other; a defect the more remarkable in one who shows so much attention to the phenomena of disease, and who for the most part allows himself to be so little warped by preconceived hypothesis. This view of the subject leads him not unfrequently to reject active and decisive remedies, when he could not reconcile their operation to his supposed indications; so that, although his practice is seldom what can be styled bad, it is occasionally defective.

There were two points in which C. Aurelianus, and the Methodics generally, decidedly opposed the doctrines and practice of the followers of Hippocrates, in trusting the removal of disease to the restorative powers of nature, and in attributing diseases to the excess or defect of particular humours. With respect to the former point, they conceived that it was as frequently necessary to oppose as to promote the natural actions of the system; and with respect to the latter, they did not admit the existence of the supposed four humours; and, even if their existence could be proved, they did not conceive that they were in possession of the means of acting upon them individually or specifically.

In the treatment of acute diseases, or those of constriction, the cure was effected by topical bleeding, (for general bleeding was rarely admitted,) and by narcotic and oleaginous applications, aided by a pure and sometimes by a moist air. Abstinence was strictly enjoined, and indeed often carried to an undue length; and in the administration of all remedies the practitioner was frequently guided by critical periods, generally of three, or in other cases of seven days. When the ordinary means of cure were found not to be successful, or when any circumstance occurred which appeared to contradict their application, C. Aurelianus had recourse to a preparatory system. This consisted principally in certain regulations regarding diet and exercise, in the use of the bath, frictions, and other external applications; when the system was thus prepared, the ordinary plan of treatment was had recourse to. Inflammatory diseases were supposed to depend upon constriction; abstinence, rest, and friction were enjoined in the first instance; bleeding general and local, baths, and certain vegetable preparations were then administered, while purgatives seem to have been seldom if ever employed. Little regard appears to have been paid to particular symptoms, and upon the whole we should be disposed to consider the practice as deficient in promptness and vigour, and not very unlike that which prevails at this day in many parts of the continent. We have mentioned above that C. Aurelianus seldom employed purgatives,—an unfortunate prejudice, by which he deprived himself of one of the most useful agents in the cure of disease; he also generally condemns the use of what are termed specifics, an error, if it be one, much more venial: he very sparingly employs diuretics, condemns narcotics, and rejects caustics and all similar applications.*

Although the Methodic sect continued to prevail among the Roman physicians during the greatest part of the two first centuries of the Christian æra, some alteration in the original tenets of Themison were gradually introduced, and it at length became subdivided into several minor sects or schools, which, although agreeing in certain fundamental principles, had each their peculiar views, which led to their separation from the main body, and to the adoption of specific appellations. Two of these were of sufficient notoriety to require being individually mentioned in this sketch, —the Pneumatics, and the Eclectics or Episynthetics.

The Pneumatics rose into notice about half a century after the death of Themison. They derive their appellation from the circumstance of their having introduced into their pathology the agency of what is termed the spirits (πνευμα), which, together with the solids and the fluids, compose the corporeal frame. It would be somewhat difficult to state, in a few words, to what supposed substance or power the term was applied; we may observe in it some traces of the pneumatic physiology of the modern chemists, while in some of its agencies it resembles the nervous influence. This sect has acquired considerable celebrity from the name of an eminent medical writer, which has been generally attached to it, that of Aretæus.

There is some uncertainty respecting both the age and the country of Aretæus; but it seems probable that he practised in the reign of Vespasian, and he is generally styled the Cappadocian. He wrote a general treatise on diseases, which is still extant, and is certainly one of the most valuable reliques of antiquity, displaying great accuracy in the detail of symptoms, and in seizing the diagnostic character of diseases. In his practice he follows for the most part the method of Hippocrates, but he paid less attention to what have been styled the natural actions of the system; and, contrary to the practice of the Father of medicine, he did not hesitate to attempt to counteract them when they appeared to him to be injurious. The account which he gives of his treatment of various diseases indicates a simple and sagacious system, and one of more energy than that of the professed Methodics. Thus he freely administered active purgatives; he did not object to narcotics; he was much less averse to bleeding; and upon the whole his materia medica was both ample and efficient. It may be asserted generally, that there are few of the ancient physicians, since the time of Hippocrates, who appear to have been less biassed by attachment to any peculiar set of opinions, and whose account of the phenomena and treatment of disease has better stood the test of subsequent experience. We have placed Aretæus among the Pneumatics, because he maintained the doctrines which are peculiar to this sect, and because he is generally considered as such by most systematic writers, although perhaps, strictly speaking, he is better entitled to be placed with the Eclectics.†

Of the sect of the Eclectics we know little except through the medium of the writings of their opponents. The most celebrated of them was

* Vide Opus. de Morb. Acut. et Chron. *Clerc*, p. ii. liv. iv. sect. 1, ch. 5-11; we have in this author a very ample account of the principles and practice of the Methodics. *Barchusen*, Diss. 11, § 5. *Haller*, Bib. Archigenes of Apamea, who practised at Rome in the time of Trajan, and enjoyed a very high reputation for his professional skill. He is, however, reprobated as having been fond of introducing new and obscure terms into the science, and having attempted to give to medical writings a dialectic form, which produced rather the appearance than the reality of accuracy. Archigenes published a treatise on the pulse, on which Galen has written a commentary; it appears to have contained a number of minute and subtile distinctions, many of which we may venture to affirm have no real existence, and to have been for the most part the result rather of a preconceived hypothesis than of actual observation; and the same remark may be applied to an arrangement which he proposed of fevers. He, however, not only enjoyed a considerable degree of the public confidence during his life-time, but left behind him a number of disciples, who for many years maintained a respectable rank in their profession. (*Clerc*, p. ii. liv. iv. sect. 2, ch. 1. *Barchusen*, Diss. 15, p. 240 et seq. *Sprengel*, t. ii. p. 75–82.)

It may appear singular that we have so many instances of individuals who have risen to great eminence, both from their professional skill and general science, but of whose private history we possess so little information. This is very remarkably the case with Celsus. We know little either of his age, his origin, or even of his actual profession. There are some incidental expressions which lead to the conjecture that he lived under the reigns of Augustus and Tiberius, and particularly the mode in which he refers to Themison would indicate that they were either contemporaries, or that Themison preceded him by a short period only. With respect to the country of Celsus, we have nothing on which to ground our opinion, except the purity of his style, which at most would prove no more than that he had been educated and passed a considerable part of his life at Rome.

With regard to his profession, there is some reason to doubt whether he was a practitioner of medicine, or whether he only studied it as a branch of general science, after the manner of some of the ancient Greek philosophers. This doubt has arisen principally from the mode in which he is referred to by Columella (De Re Rust. lib. vi. cap. 5) and by Quintilian, (Lib. xii. cap. 11,) and by his not being enumerated by Pliny among the physicians of Rome in his sketch of the history of medicine. Yet, on the other hand, it appears to us that his work bears very strong evidence that he was an actual practitioner, that he was familiar with the phenomena of disease and the operation of remedies, and that he described and recommended what fell under his own observation, and was sanctioned by his own experience; so that we conceive it, upon the whole, most probable that he was a physician by profession, but who devoted part of his time and attention to the cultivation of literature and general science.

The treatise of Celsus "On Medicine" is divided into eight books. It commences by a judicious sketch of the history of medicine, terminating by the comparison of the two rival sects, the Dogmatists and the Empirics, which has been referred to above. The two next books are principally occupied by the consideration of diet, and the general principles of therapeutics and pathology: the remaining books are devoted to the consideration of particular diseases and their treatment, the third and fourth to internal diseases, the fifth and sixth to external diseases and to pharmaceutical preparations, and the two last to those diseases which more particularly belong to surgery. In the treatment of disease, he for the most part pursues the method of Asclepiades; he is not, however, servilely attached to him, and never hesitates to adopt any practice or opinion, however contrary to his, which he conceived to be sanctioned by direct experience. He adopted to a certain extent the Hippocratean method of observing and watching over the operations of nature, and rather regulating than opposing them; a method which, with respect to acute diseases, may frequently appear inert. But there are occasions on which he displays considerable decision and boldness, and particularly in the use of the lancet, which he employed with more freedom than any of his predecessors. His regulations for the employment of bloodletting and of purgatives are laid down with minuteness and precision; and although he was in some measure led astray by his hypothesis of the crudity and concoction of the humours, the rules which he prescribed were not very different from those which were generally adopted in the commencement of the present century. His description of the symptoms of fever, and of the different varieties which it assumes, either from the nature of the epidemie, or from the circumstances under which it takes place, are correct and judicious; his practice was founded upon the principle so often referred to, of watching the operations of nature, conceiving that fever consists essentially in an effort of the constitution to throw off some morbid cause, and that, if not unduly interfered with, the process would terminate in a state of health. We here see the germ of the doctrine of the *vis medicatrix naturæ*, which has had so much influence over the practice of the most enlightened physicians of modern times, and which, although erroneous, has perhaps led to a less hazardous practice than the hypotheses which have been substituted in its room.

But perhaps the most curious and interesting parts of the work of Celsus are those which treat of surgery and surgical operations. It is very remarkable that he is almost the first writer who professedly treats on these topics, and yet his descriptions of the diseases and of their treatment prove that the art had attained to a very considerable degree of perfection. Many of what are termed the capital operations seem to have been well understood and frequently practised, and we may safely assert that the state of surgery at the time when Celsus wrote, was comparatively much more advanced than that of medicine. The Pharmacy of Celsus forms another curious and interesting part of his work, and, like his surgery, marks a state of considerable improvement in this branch of the art. Many of his formulæ are well arranged and efficacious, and on the whole they may be said to be more correct and even more scientific than the multifarious compounds which were afterwards introduced into practice, and

which were not completely discarded until our own times.*

There is one circumstance respecting Celsus which requires to be noticed—that he is the first native Roman physician whose name has been transmitted to us. Before his time all those who arrived at any degree of eminence were either Greeks or Asiatics, and it would appear that the native practitioners were either slaves or persons from the lower ranks of life, who acted in the subordinate branches of the profession.† This circumstance may be attributed partly to the low state of science in Rome, even during the period when literature had advanced to considerable eminence, and still more to the idea of degradation or servility which seems to have been attached to the exercise of any art or profession for the sake of gain. All the trades and manufactures of Rome were therefore carried on by slaves, and medicine seems to have been placed in the same class. It must, however, be observed that many individuals who were brought to Rome as slaves, either by their natural talents or by some favourable conjuncture of circumstances, overcame the disadvantages of their situation, and made considerable acquirements in different departments of knowledge, and among others in that of medicine. One of the most celebrated of these is Antonius Musa, who was appointed physician to Augustus, and obtained great celebrity from his practical skill: we are told that he was a pupil of Themison, and it appears that he remained attached to the Methodic sect. (*Haller*, Bib. Med. t. i. p. 150, 1. *Eloy*, in loco. *Aikin's* Gen. Biog. in loco.)

Before we close this part of our history, it will be necessary to take some notice of a class of writers, whose names or works are transmitted to us, who particularly devoted themselves to the improvement of pharmacy. The first of these was Scribonius Largus, who flourished in the reign of Claudius. He appears to have been, like Musa, originally a slave, and it may be conjectured from his work "On the Composition of Medicines," which has been transmitted to us, that he was never able to supply the deficiency of his education. It is a mere collection of nostrums and formulæ, without arrangement or discrimination, and is solely valuable as indicating the state of the art at the time of its publication. (*Haller*, Bib. Bot. t. i. p. 76, 7, and Bib. Med. lib. i. § 51, t. i. p. 166, 7. *Eloy*, in loco. *Sprengel*, t. ii. p. 55.)

Andromachus, a native of Crete, who lived under the reign of Nero, is principally known to posterity as the inventor of certain compounded pharmaceutical preparations, one of which, the theriaca, obtained so much celebrity as to have been retained in our pharmacopœia until the close of the last century. It was composed of no less than sixty-one ingredients, which were combined together with much ceremony and no inconsiderable degree of labour and skill. Its essential ingredient, from which it derived its name, was the dried flesh of vipers, against the bites of which animals it was supposed to be an antidote. But its supposed medical virtues were equal to the number of articles of which it consisted, so that there was scarcely a disease for which the theriaca of Andromachus has not been proposed as a remedy. Andromachus is further remarkable as being the first individual on whom the title of Archiater, or principal physician, was bestowed by the emperors, a title which was continued for several centuries. (*Clerc*, par. 3, liv. ii. ch. 1. *Eloy*, in loco. *Haller*, Bib. Med. lib. i. § 56, t. i. p. 178, 9.)

We have next to notice an author of just celebrity, whose writings form one of the most valuable remains of antiquity—Pliny the naturalist. Although not attached to the medical profession, and even, as appears from many of his remarks, by no means favourably disposed to it, in various parts of his great work he affords us much important information, both direct and indirect, respecting the history of medicine in all its branches, and more especially in all that concerns materia medica and pharmacy.‡ We meet with a great number of curious facts and remarks upon these subjects, so that we are enabled from them to form a tolerably complete conception of the state of medical science in the age in which he wrote. We learn from his works that the ordinary practice was in a considerable degree what may be termed empirical, consisting in the application of certain remedies for certain diseases, without any inquiry into their mode of operation. The materia medica, which was extensive, consisted principally of vegetable products, and these combined together in various forms, but without any regard to what we should now regard as scientific principles, either chemical or pharmaceutical. We find that they possessed various active remedies, adapted for the greatest part of the most important indications, so far as they could be obtained from vegetable or animal substances, but that in the application of them they frequently proceeded upon incorrect principles.

Another writer who lived about the same time with Pliny, and who, although less distinguished for general science, holds a conspicuous rank among the medical authors of this period, is Dioscorides. The same obscurity hangs over every thing which regards the personal history of Dioscorides as over that of so many individuals to whom we have had occasion to refer. It was generally supposed that he was a native of Asia Minor, and that he was a physician by profession. It appears pretty evident that he lived in the second century of the Christian era, and as he is not mentioned by Pliny, it has been supposed that he was a little posterior to him. The exact age of Dioscorides has, however, been a question

*Clerc, par. 2, liv. iv. sect. 2, ch. 4, 5. *Barchusen*, diss. 15, p. 231, 2. *Morgagni*, Epistolæ in Celsum. *Haller*, Bib. Med. t. i. § 49. *Eloy* in loco. Nouv. Dict. Hist. in loco. *Sprengel*, t. ii. p. 25–8. *Black's* Hist. of Medicine, p. 63–82. *Goulin*, Encyc. Méth. "Médecine," in loco. *Petit-Radel*, Biog. Univ. "Celse."

† *Clerc*, par. 3, liv. i. ch. 2. The condition of the practitioners of medicine in Rome was the subject of a learned controversy between Mead and Middleton; see Life of Mead, prefixed to his works, v. i. p. 13, Edin. 1765, and Aikin's Gen. Biog. art. "Middleton."

‡ The late illustrious naturalist Cuvier has formed what we conceive to be a very just and candid estimate of the literary and philosophical character of Pliny, Bibl. Univ. t. xxxv. in loco; the same inserted into the translation of Pliny by M. Aj. de Grandsagne, t. i. p. lxxxv. See *Eloy*, in loco, for a list of the various editions, &c. of Pliny; he enumerates one hundred and ten, of which it is worthy of notice that only two were printed in England. *Haller*, Bib. Bot. t. i. p. 91–8.

of much critical discussion, and we have nothing but conjecture which can lead us to decide upon it. He has left behind him a treatise on the materia medica, a work of great labour and research, and which for many ages was received as a standard production. The greater correctness of modern science, and the new discoveries which have been made, cause it now to be regarded rather as a work of curiosity than of absolute utility; but in drawing up a history of the state and progress of medicine, it affords a most valuable document for our information. His treatment consists of a description of all the articles then used in medicine, with an account of their supposed virtues. The descriptions are brief, and not unfrequently so little characterized as not to enable us to ascertain with any degree of accuracy to what they refer, while to the practical part of his work the same remark nearly applies that was made above with respect to Pliny, that it is in a great measure empirical, although his general principles, so far as they can be detected, appear to be those of the Dogmatic sect. The great importance which was for so long a period attached to the works of Dioscorides, has rendered them the subject of almost innumerable commentaries and criticisms, and even some of the most learned of our modern naturalists have not thought it an unworthy task to attempt the illustration of his Materia Medica. Upon the whole we must attribute to him the merit of great industry and patient research, and it seems but just to ascribe a large portion of the errors and inaccuracies into which he has fallen, more to the imperfect state of science when he wrote, than to any defect in the character and talents of the writer.*

CHAPTER V.—*Account of the opinions and practice of Galen—History and Education of Galen—Remarks on his character and writings—His physiology, anatomy, pathology, and practice.*

The course of our narrative brings us to one of those extraordinary characters who are destined to form an æra in the history of science, both from the actual improvements which they have introduced into it, and from the ascendency which their genius enabled them to acquire over the minds of their contemporaries. Of these, one of the most remarkable that ever appeared either in ancient or in modern times, is Galen. Galen enjoyed both from birth and from education every natural and acquired advantage; his father was a man of rank, and his education appears to have been conducted upon the most liberal and judicious plan. He studied philosophy in the various schools that were then in the highest estimation, and without exclusively attaching himself to any one of them, he is said to have taken from each what he conceived to be the most important parts of their systems, with the exception of the Epicurean, the tenets of which he entirely rejected. His professional studies were conducted upon an equally extensive plan; he attended the various schools and travelled through different countries for the express purpose of acquiring information, but it may be presumed that his knowledge of medicine was principally acquired at Alexandria, which still retained its character as the great depository of medical science. After passing a few years at his native city of Pergamus, spending some time at Rome, and again at Pergamus, he finally returned to Rome in consequence of the express request of the Emperor Aurelius, and made that city his residence for the remainder of his life.

The works which Galen left behind him are very numerous, amounting in the whole to about two hundred distinct treatises; they are all on subjects directly or indirectly connected with medicine, and exhibit a great extent of knowledge on the subjects of which he treats, and a degree of information, as far as we can judge, greater than that of any of his contemporaries. He appears also to have been a man of a superior mind and of a very decided character; confident in his own powers, and paying but little attention to the opinions of others. Hence he may be accused of arrogance and of want of candour, and he can only be defended upon the principle that he was so far in advance of his contemporaries as to be fully convinced of the futility of their reasoning and the deficiency of their information. The result was that he gained that superiority over his contemporaries which he assumed, and actually acquired a sway over public opinion on all points connected with medicine which has never been obtained by any individual either before or since his time. The rank which Galen held in the medical world has been compared not unaptly to that which Aristotle possessed in the world of general science. For centuries after his death his doctrines and tenets were regarded almost in the light of oracles, which few persons had the courage to oppose; and all the improvements in medicine which were even contemplated, consisted of little more than illustrations of his doctrines or commentaries on his writings. In numberless instances it was deemed a sufficient argument, not merely against an hypothesis, but even against an alleged matter of fact, that it was contrary to the opinion of Galen; and it may be stated without exaggeration that the authority of Galen alone was estimated at a much higher rate than that of all the medical writers combined who flourished during a period of more than twelve centuries.

Although such a brilliant reputation might in some measure depend upon accidental circumstances and upon the mere personal character of the individual, we may fairly presume that there must have been a foundation of a more solid nature; and upon an actual survey of the writings of Galen, we shall find ample reason to conclude that he was a man of great talents and of very extensive acquirements. In his general principles he may be considered as belonging to the Dogmatic sect, for his method was to reduce all his knowledge, as acquired by the observation of facts, to general theoretical principles. These principles he indeed professed to deduce from experience and observation, and we have abundant proofs of his diligence in collecting experience, and his accuracy in making observations. But

* *Cicre*, par. 3, liv. ii. ch. 2. *Eloy*, in loco, where we have an account of the various editions, comments, translations, &c. *Sprengel*, t. ii. p. 58-64. *Ackermann*, p. 4, cap. 19. *Haller*, Bib. Bot. t. i. p. 79-87. *Goulin*, Encyc. Méth. Médecine, "Dioscoride." *Du-Petit-Thouars*, Biog. Univ. in loco.

still, in a certain sense at least, he regards individual facts and the detail of experience as of little value, unconnected with the principles which he laid down as the basis of all medical reasoning. In this fundamental point, therefore, the method pursued by Galen appears to have been directly the reverse of that which we now consider as the correct method of scientific investigation, and yet such is the force of natural genius, that in most instances he attained the ultimate object in view, although by an indirect path. He was an admirer of Hippocrates, and always speaks of him with the most profound respect, professing to act upon his principles, and to do little more than to expound his doctrines and support them by new facts and observations. Yet in reality we have few writers whose works, both as to substance and manner, are more different from each other than those of Hippocrates and Galen, the simplicity of the former being strongly contrasted with the abstruseness and refinement of the latter. Those of his works which are the most truly valuable, and in which he actually rendered the greatest service to science, are his treatises on physiology. The knowledge which he possessed on this subject was much more considerable than that of any of his contemporaries; in all that regards the operations of the animal economy he was much better acquainted with the facts, and much more ingenious in the application of them. He appears to have been well practised in anatomy, and especially in what may be termed pathological anatomy he far surpassed any of the ancients. His knowledge of particular structures was in many respects correct, and in his mode of classifying them he made no inconsiderable approach to the philosophical views which have been taken of them by the anatomists of the present day. It appears upon the whole probable that he was not in the habit of dissecting the human subject, and, indeed, this may be fairly inferred from his own remarks; but there is reason to suppose that he omitted no opportunity of examining the structure of those animals which the most nearly resemble it, and that from them he has drawn up his descriptions. Considering this radical defect, it must be admitted that they possess great merit, and we may justly express our surprise at the few points in which they betray the imperfections of their origin. (*Douglas*, Bibliog. p. 18–22.)

The pathology of Galen was much more imperfect than his physiology, for in this department he was left to follow the bent of his speculative genius almost without control. He adopts, as the foundation of his theory, the doctrine of the four elements, and, like Hippocrates, he supposes that the fluids are the primary seat of disease. But in his application of this doctrine he introduced so many minute subdivisions and so much refined speculation, that he may be regarded as the inventor of the theory of the Humoralists, which was so generally adopted in the schools of medicine, and which for so long a period entirely engrossed their attention. The four elements, the four humours, and the four qualities, connected in all the variety of combinations, presented a specious appearance of method and arrangement, which took such firm possession of the mind as to preclude all inquiry into the validity of the foundation, and to present us with one of the most remarkable examples of the complete prostration of the understanding in a physical science, where facts were daily obtruding themselves upon observation, but were either unnoticed or totally disregarded.

The practice of Galen in its general character appears to have been similar to his pathology, and, indeed, to have been strictly deduced from it. His indications were in exact conformity to his theory, and the operation of medicines was reduced to their power of correcting the morbid states of the fluids, as depending upon their four primary qualities or the various modifications of them. Many parts of his writings prove that he was a diligent observer of the phenomena of disease, and he possessed an acuteness of mind which well adapted him for seizing the most prominent features of a case, and tracing out the origin of the morbid affection. But his predilection for theory too frequently warped and biassed his judgment, so that he appears more anxious to reconcile his practice to his hypothesis than to his facts, and bestows much more labour on subtile and refined reasoning than on the investigation of morbid actions or the generalization of his actual experience.

The number of treatises which Galen left behind him is very considerable, amounting to nearly two hundred separate works, embracing every department of medical science. His style is generally elegant but diffuse, and as may be imagined from the multiplicity of his works, he frequently repeats and copies from himself. Considered under the two classes of anatomy and physiology, and of pathology and practice, the following may, perhaps, be selected as the most valuable, both with respect to the absolute addition which they made to the previous stock of knowledge, and as to the reasoning employed in them. Under the first head we may select the treatise "On the Use of the Parts of the Body," in seventeen books, in which he describes the structure of the different organs, and assigns to each of them their use. This is a work of great anatomical research and physiological ingenuity, which contains many facts that were probably the result of his own investigation, and exhibits a very favourable specimen of his reasoning powers, when not too much under the influence of preconceived hypothesis. The same kind of merit, although less in degree, may be assigned to the treatise "On the Motion of the Muscles," and also to that "On the Formation of the Fœtus," making due allowance for the greater difficulty and obscurity of the subject.

Among the works of the second class the treatise "On Temperaments" has been greatly and justly celebrated, as well as that "On the Seat of Disease," while that "On the Varieties of the Pulse" affords a happy illustration of his peculiar turn of mind, of his acuteness and originality, and at the same time, of his devoted attachment to hypothesis. The two works, "On the Differences and the Causes of Diseases," and "The Method of Cure," are more especially interesting, as containing the most detailed view of his peculiar doctrines of the humoral pathology, of the indications of cure which he laid down, and the

methods which he adopted for their accomplishment. These two latter works exhibit a very complete view of the practice of Galen and of that of his contemporaries, and enable us to form a correct opinion of the state of the science when he entered upon the study of it, and of the additions which he made to it. To attempt an analysis of the works themselves or of the details of Galen's practice, would carry us far beyond the limits of this treatise, and, indeed, it would be principally as a question of literary curiosity that such an examination could be sustained. Their general character may be understood from what has been stated above, and we fully coincide in the remark of a learned and impartial critic, the late Dr. Aikin, who, after giving full credit to Galen for talent and acquirements, thus concludes:—"His own mass and modern improvements have now in great measure consigned his writings to neglect, but his fame can only perish with the science itself." The remark which we formerly made with respect to Hippocrates applies equally to Galen, that the great superiority which he acquired over his contemporaries appeared to repress all attempts at farther improvement.*

CHAPTER VI.—*An account of the successors of Galen—Decline of medical science—Sextus Empiricus—Oribasius—Ætius—Alexander Trallianus—Paulus Eginetus—Account of the state of medicine among the Arabians—Conquests of the Arabians—Their patronage of science—Invention of chemistry—Ahrun—Serapion—Alkhendi—Rhazes—Ali-Abbas—Avicenna—Mesue—Albucasis—Avenzoar—Averroes—Estimate of the merits of the Arabic school.*

In investigating the state of medicine during the middle ages, it is apparent than mankind seemed to be satisfied with the progress which had been made in the science, or were conscious of their inability to surpass the limits which had been assigned to it; and the result was, that after the death of Galen we have few illustrious names to celebrate, and no discoveries to record. Literature in general was now, indeed, rapidly declining, and various causes both moral and political were coming into operation, which suspended the progress of science and learning for many centuries, and produced what are justly and emphatically denominated the dark ages. Into these causes it is not our business to inquire; it may be sufficient to remark that they were of so universal a nature as to operate on the human mind generally, and therefore to affect every intellectual pursuit. Medicine, among others, felt their paralysing influence, although, from certain incidental circumstances to be hereafter noticed, it was not allowed to remain so completely stationary as most of the other branches of science.

About the period when Galen flourished, the Roman empire began to exhibit very decided symptoms of that decline which, proceeding with more or less rapidity, was never altogether suspended until it terminated in complete destruction. Even in the most splendid state of Rome, the cultivation of science was very limited, and we have had occasion to remark that almost all the physicians who acquired any considerable degree of celebrity were natives of Greece or Asia, and wrote in the Greek language. This was the case with Galen himself and with the few individuals who succeeded him, whose names are of sufficient importance to be introduced into this sketch. The medical writers of the third and fourth centuries have been characterized by Sprengel as "de froids compilateurs, ou d'aveugles empiriques, ou de foibles imitateurs du médecin de Pergame." (T. ii. p. 170. Jourdan's Transl.)

The only exception to this remark is Sextus Empiricus, who appears to have been a contemporary of Galen, and probably derived his appellation from the sect to which he attached himself, as there are some treatises of his still extant in which he attacks the principles of the Dogmatists with considerable acuteness. We may conclude from his works that he was a man of learning and talents, well versed in the principles of the philosophers, and familiar with all the branches of literature and science which were cultivated in his time. (*Enfield*, v. ii. p. 136.) He is, however, the last medical writer to whom the character of Sprengel does not strictly apply. Oribasius, who lived in the fourth century, Ætius in the fifth, Alexander Trallianus in the sixth, and his contemporary Paulus, were all zealous Galenists, who professed to little more than to illustrate or comment on the works of their great master. Their writings are principally compilations from their predecessors; they are, however, occasionally curious from the incidental facts which they contain, and by furnishing us with extracts or abstracts of treatises which are no longer extant; but this constitutes almost their sole value. The only additions to the practice of medicine which they afford are an account of certain surgical operations, which is given us by Ætius, and a treatise by Paulus on midwifery, which is more complete than any that had previously appeared, and was long held in high estimation. But even these, which form but a small portion of the whole of their works, are connected with so much credulity and superstition, as to indicate at least the most degraded state of the science, if not the defective judgment of the writer. Ætius expressly recommended the use of medical arts and incantations, and that, not, as has sometimes been done in a more enlightened age, from a knowledge of the effect they might produce on the imagination of the patient, but apparently from his own opinion of their physical operation on the system. (*Conring*, cap. 3, sect. 18-20. *Sprengel*, sect. 6, ch. 1-3.) It must, however, be admitted that both in Alexander Tallianus and in Paulus we meet with various descriptions of disease, which indicate that they possessed the talent of accurate observation; and we may conclude that, although in what respects opinions they were the devoted followers of Galen, yet in the simple detail of facts their au-

* *Conring*, Introd. cap. 3, sect. 16; cap. 4, sect. 17, et alibi. *Clerc*, par. iii. liv. iii. ch. 1—8, contains a very ample account of all that regards the writings and opinions of Galen. At this period we lose the farther aid of this candid and judicious historian of medicine. *Earchusen*, Diss. No. 16, Nouv. Dict. Hist. "Galien.," *Haller*, Bib. Med. lib. i. sec. 80, 1. *Lauth*, liv. v. par. 1. *Sprengel*, sect. 5, ch. 6. *Ackermann*, cap. 21, 2. *Blumenbach*, Introd. sect. 75. *Goulin*, Encyc. Méth. Médecine, "Galien." *Renauldin*, Biog. Univ. "Galien."

thority may be relied upon with considerable confidence.*

With the death of Paulus, which took place about the middle of the seventh century, we may date the termination of the Greek school of medicine, for after his time we have no work written in this language which is possessed of any degree of merit. Those which occasionally appeared were mere servile transcripts of Galen and his disciples, or compilations formed without judgment or discernment, devoid of original observation, or even at any attempt at generalization or arrangement. To this degraded state was the science of medicine reduced in the former seats of learning, when a new school arose in a different quarter of the world, which will require our attention, from the actual additions which it made to our knowledge, as well as from the mode of its origin and the nature of its connection with the Grecian and Roman schools.

The city of Alexandria still retained its reputation as the great school of medicine, partly resting its fame on the excellence of its former professors, and in some measure depending on the value of its extensive library and other institutions favourable to the cultivation of science, the forms of which at least were still preserved. But even these feeble remains were destroyed by the conquest of the Arabians in the seventh century, who in the genuine spirit of blind bigotry appeared to be actuated by the barbarous desire of totally eradicating science from the face of the earth. The catastrophe which befel the Alexandrian library is too well known to be repeated in this place; a calamity, the full extent of which can scarcely be appreciated by one who is in the habit of regarding literature only as it exists in modern times, when books of all descriptions are multiplied to an excessive degree, and when the loss occasioned by the most splendid collection would be nearly confined to a single nation or community. It appears, however, that notwithstanding the brutal violence of the Saracen invaders, some books escaped from the general wreck of literature and science, and that there were not wanting some individuals who were capable of estimating their value. Among these relics were the writings of Galen, and we are informed that at an early period of the Saracenic empire they began to be held in very high estimation; they were translated into the Arabic language, were commented upon and elucidated in various ways, and soon acquired a degree of celebrity scarcely short of what they had previously enjoyed among the Greeks themselves. The Arabians were also in possession of the works of Hippocrates, but the simplicity of this author was less adapted to their taste than were the metaphysical refinements and elaborate arrangements of Galen, so that, while the latter was regarded with a respect amounting almost to veneration, the former was little read or estimated.

After the immediate successors of Mahomet had completed their conquest of a considerable part of the civilized world, they rested from their warlike triumphs, and seemed disposed to add to the splendour of their empire by the cultivation of the arts of peace. The patronage of literature was an express object of many of their rulers, and even the works of the Greek philosophers were translated and studied with much assiduity. But the spirit of Mahomedanism was decidedly averse to intellectual improvement, and we accordingly find that no additions were made to general science, and that very little was accomplished even in the collection of facts and observations. To this remark, however, medicine forms an exception; for although the Arabian physicians adopted implicitly all the theories and speculations of Galen, and seldom ventured in the smallest degree to deviate from his practice, we are indebted to them for the description of some diseases, which either made their first appearance about this time, or had not been before specifically noticed.†

We have to notice, in this place, a curious occurrence in the history of science, and one which indirectly produced a very important effect upon the subject of this dissertation—the invention of chemistry. The origin of chemistry, like that of all other sciences, is obscure and uncertain. Traces of what may be called chemical operations are to be found even among the Jews and Egyptians, but it is generally admitted that they are to be regarded as incidental occurrences, depending upon accidental observations, pursued no further than the object immediately in view, and not considered, even by those who practised them, as more than mere insulated facts, leading to no general principles nor to any farther investigations. The practice of chemistry as a distinct pursuit seems to have originated with the Arabians, and by them was made subservient to the purposes of medicine. (*Freind*, pars 2, sub init. *Sprengel*, t. 2. p. 246-266.) It is not our business to inquire into the mode in which this art took its first rise, or to trace its subsequent progress, except so far as may be connected with our present subject; and this will be the most conveniently accomplished by giving in succession a brief account of the most distinguished writers who belonged to the Arabian school of medicine.

The earliest Arabian writer on medicine of whom we have any certain account, would appear to be Ahrun, who was a priest at Alexandria. He published a treatise entitled "Pandects;" it has not come down to us, but it deserves to be noticed as it is said to have contained the first description of the small-pox. He was contemporary with Paulus, and from the account of his works which has been transmitted to us by Rhazes, we may conclude that the science of medicine was cultivated at that time with at least as much success among the Arabians as among the Greeks. During the next three centuries, although we meet with the names of many individuals who acquired a certain degree of temporary celebrity, we have none who rendered themselves so far pre-eminent as to entitle them to particular notice in this brief sketch. The first author of whom it will be necessary to give any distinct account is Serapion; he lived in the ninth century, and is said to have been a native of Damascus. His treatise entitled,

* *Freind*, Hist. Med. p. 398 et seq., and p. 420 et seq. Opera a Wigan, Lond. 1733. *Eloy*, "Paul d'Egine." *Haller*, Bib. Med. t. i. p. 311-15.

† For an account of the Arabian school of medicine generally, the reader is referred to Freind, who treats upon every thing connected with it in the most ample manner. See also *Barchusen*, diss. 17, sec. 12 et seq. *Sprengel*, sect. 6, ch. 5. *Cabanis*, sec. 6.

according to the fancy of the translators, "Aggregator," "Breviarium," or "Therapeutica Methodus," was written originally in Syriac; its professed object was to give a complete system of the Greek medicine, and to incorporate with it the principles and practice of the Arabians. Like those of the rest of his countrymen, the greatest part of Serapion's work is taken from those of his predecessors, and particularly from Galen; but it contains some few novelties with respect both to doctrine and to practice; and in one point, the preparation and composition of medicines, as well as in the articles employed, we may notice a decided improvement. (*Haller*, Bib. Bot. t. 1, p. 183–9.)

At the same time with Serapion lived Alkhendi, a multifarious writer, who obtained a very high degree of celebrity among his contemporaries, perhaps more from the variety of his acquirements than from the excellence he attained in any particular department. He is said to have assiduously cultivated mathematics, and the various branches of natural philosophy as well as medicine; and among other subjects to which he particularly directed his attention, we find astrology expressly enumerated. In relation to his varied attainments, he was styled the subtile philosopher, the learned physician, and the Greek astrologer. As an example, both of the spirit of the age and of the genius of the individual, we may remark that Alkhendi applied the rules of geometrical proportion and of musical harmony to regulate the doses of medicine, and to explain the mode of their operation—a mistaken application of science, which, however gross it may now appear, we must reflect was not entirely exploded until long after the revival of letters.*

We now come to one of the most illustrious of the Arabian school, Rhazes. He was born at Irak in Persia, in the ninth century; is described as a person of varied acquirements, as being well versed in general science, and, as his writings demonstrate, of unwearied industry. There is some reason to doubt whether the principal work which has been transmitted to us under his name, entitled "Continens," is precisely in the form in which it was left by its author; but there appears to be sufficient proof of its general authenticity to enable us to deduce from it, as well as from his other acknowledged works, an ample and correct view of the opinions and practice both of Rhazes himself and of his contemporaries. For the most part, the writings of Rhazes are deficient in method and arrangement, and they consist principally of abstracts and comments on Galen and the Greek physicians; but they also contain observations that appear to be original, and we even meet with the description of some diseases which were either new, or at least were not noticed by the ancients. Rhazes gives us a correct and elaborate description of the small-pox and measles, detailing the theory which was formed of their nature and origin by the Arabians, and the treatment which they employed. The most curious and original work of Rhazes is his "Aphorisms," in one part of which he professedly gives the result of his own observation and experience. But even this treatise, which was long regarded as of the highest authority in the schools of medicine, contains little that is really new or valuable; and when we compare it with its celebrated prototype, we cannot but be impressed with the very small advance which had been made in the science and practice of medicine during a space of nearly thirteen centuries. The most important additions which Rhazes made were, perhaps, rather in surgery and in pharmacy than in medicine strictly so called; and it is worthy of notice, that in the latter department we have some of the earliest indications of the free employment of what were styled the chemical remedies. (*Freind*, p. 483–91. *Haller*, Bibl. Med. Prac., lib. ii. § 135. *Eloy*, in loco. *Lauth*, p. 280–2. *Sprengel*, t. ii. p. 285–301.)

A short time after Rhazes lived Ali-Abbas, a writer of considerable celebrity, who obtained the appellation of the magician. His principal work, entitled "Opus Regium," professes to contain a complete view of the state of medicine in all its branches; it consists chiefly of abstracts of the doctrines and opinions of the Greek physicians, but along with these are contained some original observations. At the time of its publication it was very highly estimated, and perhaps may be considered as possessing more real value than most of the works that proceeded from the Arabian school. (*Freind*, p. 481. *Haller*, Bib. Med. lib. ii. § 137, t. i. p. 380. *Sprengel*, t. ii. p. 301–5.)

The fame of Ali-Abbas was, however, almost entirely eclipsed by that of Avicenna,† who flourished about a century later, and who rose to the highest pitch of celebrity, so as to be regarded by his countrymen as superior to Rhazes, or even to Galen himself. Avicenna was born at Bochara in the year 980, and was carefully educated in all the learning of the times, consisting principally of the Aristotelian logic and dialectics, with the imperfect mathematical and physical science, that was then taught in the schools of Bagdat. He appears to have been possessed of an ardent desire for acquiring knowledge, and of great industry, but united to a portion of fanaticism, indicative of a defective judgment, and fostered by the spirit of the age, which induced him to conceive himself under the influence of supernatural revelation. After a foundation of general science he entered upon the study of medicine, which he prosecuted with the same diligence and with the same spirit of enthusiasm. His reputation became so high that he was early introduced to the court, and for some years was without a rival in his profession. His death, which took place in his fifty-sixth year, was probably hastened by some political intrigues, in which he unfortunately became entangled.

The works which Avicenna left behind him are numerous, and embrace both general science and medicine. The former long maintained a high character for extent of information and profundity of learning, and according to the standard of the age were probably entitled to this commendation. But his fame, both with his contemporaries and with posterity, principally rests upon his great

* For an account of the earlier writers of the Arabian school, see *Freind*, Hist. Med. pars 2, sub init.

† The actual name of this individual is said to have been Al-Hussain-Abou-Ali-Ben-Abdallah-Ebn-Sina. *Sprengel*, t. ii. p. 305. In most cases it appears that the names by which the Arabians are generally known in Europe were not their real names.

medical work, entitled, "Canon Medicinæ," which may be regarded as a kind of encyclopædia of all that was then known of medicine, and of the sciences connected with it, anatomy, surgery, therapeutics, and botany. Its celebrity was so great as to have acquired for its author the title of prince of physicians; for some centuries it was the received text-book in most of the medical schools, both of the Arabians and the Europeans; until the revival of letters it superseded, in a great measure, the works even of Galen, it produced scarcely less numerous commentaries and epitomes, and had not entirely lost its authority two centuries ago. Yet the matured judgment of one of the most learned and candid of the modern critics has not hesitated to bestow upon this so much vaunted production the character of an ill-digested and servile compilation, containing little that is new either in the way of observation or of practice. Indeed, the sole aim of Avicenna seems to have been to collect matter from all quarters, without paying any regard to its value, or to the mode in which it was arranged. He was a devoted admirer of Aristotle and Galen, and seemed to imagine that the ultimate object either of the philosopher or the physician consisted in being intimately acquainted with their writings, and in defending them against all objections. Upon the whole, after making every allowance for the period in which he lived, it seems difficult to account for the very great credit which he acquired, not only during his life-time, but which was attached to his writings after his death; a credit so much greater than what they merit, either from the importance of the information which they contain, or the mode in which it is conveyed.*

There are two Arabian writers of the name of Mesue, whose celebrity entitles them to a brief notice in this place, although considerable uncertainty attaches to both their individual history and to their works. The elder of them is said to have lived in the eighth, and the younger in the tenth century; and they are both represented as being Christians of the Nestorian sect, but to have exercised their profession at Bagdat. The elder Mesue is principally remarkable as having been among the first who made correct translations of the Greek physicians, and especially of Hippocrates and Galen, into Arabic; for although he appears to have composed many original works, we do not find that they rose into any high repute even among his contemporaries. To the younger Mesue is usually ascribed a treatise on materia medica and pharmacy, which for a long time was in great estimation, and was republished and commented upon even as late as the sixteenth century; it probably contained a full view of the state of the science when he wrote, and is interesting, as it indicates the introduction of several new remedies into medicine; but in other respects it is to be regarded merely as a literary curiosity. (*Freind*, p. 481, 2. *Haller*, Bibl. Med. Prac. lib. ii. § 126. *Eloy*, in loco. *Enfield*, v. ii. p. 213. *Sprengel*, t. ii. p. 325.)

The last of the Arabians who acquired any considerable distinction as a writer on medical subjects, is Albucasis. So little is known of his personal history, that both his birth and the country in which he lived have been the subject of controversy, and appear to be entirely conjectural. His principal works are on surgery; and the reputation which he acquired in this department is almost as great as that of Avicenna in medicine. He seems to have been a man of learning and talents, to have made himself master of the writings and practices of his predecessors, and to have improved upon them. The description which he has left of his operations shows him to have possessed a degree of boldness and dexterity which could only exist in one who was well acquainted with his art, and had been habituated to the practice of it. His practice was what we should now consider as unnecessarily severe, making much more use of the knife and of the actual cautery than is done in modern times, and in all respects inflicting both more pain and more permanent injury on his patients. The works of Albucasis appear, however, to have afforded by far the most complete view of the practice of surgery which then existed; and from this circumstance, as well as from their real merit, they were, for many ages, considered as standard performances, and employed as the text-book in various schools and colleges. (*Freind*, p. 506–524, 2. *Haller*, lib. ii. § 148. *Eloy*, in loco. *Lauth*, p. 285, 6. *Sprengel*, t. ii. p. 327–32.)

It remains for us to give an account of two individuals, who, although natives of Spain, and residing principally in that country, were of Saracenic origin, and wrote in the Arabic language—Avenzoar and Averroes. Avenzoar was born at Seville, in the end of the eleventh century, and is said to have lived to the unusual length of one hundred and thirty-five years; but probably some error may have crept into this statement in consequence of both his father and his son having been, like himself, engaged in the practice of medicine. His principal work, entitled "Thaissyr,"† which consists in a general compendium of medical practice, displays more originality and discrimination than the writings of any of the native Arabians; so that, although he was professedly a disciple of Galen, he does not hesitate, on certain occasions, to shake off his authority when his opinions or practice were not sanctioned by his own experience. We may collect, from certain parts of his works, that he practised both surgery and pharmacy, as well as medicine properly so called; and we have many valuable observations on each of these departments. Upon the whole, we may consider Avenzoar as respectable both from his general character and his professional skill, and entitled to our regard as one of the improvers of his art. (*Freind*, p. 492–503. *Haller*, lib. ii. § 142. *Eloy*, in loco. *Sprengel*, t. ii. p. 332–7.)

Besides the reputation which Avenzoar derived from his own merits, he was perhaps still more known among his countrymen as being the preceptor of the celebrated Averroes. Averroes was a native of Corduba, and flourished in the twelfth

* *Freind*, lib. ii. p. 491–2. *Haller*, Bib. Med. lib. ii. § 139. *Eloy*, in loco. *Lauth*, p. 282–5. *Enfield*, v. ii. p. 222, 3. *Sprengel*, t. ii. p. 305–22. *Hutton's* Math. Dict., in loco. *Goulin*, Encyc. Méth. Médecine, "*Avicenne.*" "*Avicenne,*" in Biog. Univ.

† Freind designates the Thaissyr as "liber qui omnia victus et medicinæ præceptæ in plerisque morbis contineret:" p. 493.

century; he was of illustrious birth, and highly educated in all the branches both of literature and of science which were then taught in the Saracenic colleges of Spain. From certain political causes he was, in the early part of his life, the subject of religious persecution; but he succeeded in repelling the attacks that were made upon his faith, and was finally reinstated in all his former honours and in the public estimation. These circumstances, coinciding probably with the peculiar temperament of his mind, gave to his character a degree of ascetic gloom and austerity; but he appears to have been a man of distinguished worth and of superior abilities. Averroes' professional occupations were principally in a civil capacity; he is therefore to be regarded, not as a practitioner, but as a scholar who pursued the study of medicine as a branch of physical science. But such was his ardour in the pursuit of general knowledge, and the fondness which he manifested for this particular department, that he made himself intimately acquainted with it in all its details, and in his great work entitled "The Universal," he shows that he was not deficient in any part of the science which could be acquired by the mere study of books. As a philosopher he was a zealous and obscquious follower of the opinions of Aristotle, and as a physician, of those of Galen; he published many comments on both of them, which acquired the highest degree of reputation, and for many ages were considered as standard performances. Yet there is reason to suppose that he was ignorant of the Greek language, and, like his contemporaries, became acquainted with Aristotle and Galen only through the medium of Arabic translations. The great estimation in which the works of Averroes were held is proved by the number of editions of them which were published from time to time, one of which appeared at Venice so late as the commencement of the seventeenth century. With respect to his medical writings, as they do not profess to be the result of original observation, we cannot be surprised that their reputation is no longer supported. They are indeed entirely neglected; and it may be affirmed that, notwithstanding the celebrity which they once enjoyed, and which they so long maintained, they have not left a single permanent addition to the science.*

With Averroes terminated the Arabic or Saracenic school of medicine; after his time we have no writer whose name is sufficiently distinguished to deserve particular mention: even the study of the ancients began to be neglected, while no original observations were made, and no novel opinions or speculations were framed which might tend to excrcisc the mind or dissipate the darkness which now covered all parts of the world.

If we inquire into the causes of the great celebrity of the Arabian school of medicine, we shall be led to the conclusion that they were rather incidental and factitious than derived from its absolute merits. It has been justly observed that a considerable portion of this celebrity must be ascribed to the comparative condition of the neighbouring countries. From the eighth to the twelfth centuries was, perhaps, the period in which Europe was in the state of the most complete barbarism and superstition. The only remains of a taste for literature and science, or for the fine arts, were found among the Moors and Arabs; and it was from this source, by the intervention of the crusaders, and the intercourse which was thus effected between the Asiatics and the Europeans, that the philosophical and medical writings of the Greeks were first made known to the inhabitants of Italy and of France. And even after their introduction into Europe, it appears that they were for some time read only in Arabic translations, or in Latin versions made from these translations; so that it was not until a considerably later period that they were perused in their native language. Indeed so completely was the study of the Greek tongue suspended during the dark ages, that it may be doubted whether the writings of the ancient physicians might not have been entirely lost to posterity had they not been preserved in these translations.

There are, however, two points in which the Arabians conferred a real obligation upon their successors, the introduction of various new articles into the materia medica, and the original description of certain diseases. The additions which the Arabians made to pharmacy consisted partly in the vegetable products of the eastern or southern countries of Asia, which were only imperfectly known to the Greeks, and with which they had no intercourse. Among other substances we may enumerate rhubarb, tamarinds, cassia, manna, senna, camphor, various gums and resins, and a number of aromatics, which were brought from Persia, India, or the oriental isles. But a still more important addition which they made to the pharmacopœia consisted in what were styled chemical remedies, such as were produced by some chemical process, in opposition to those substances that were used nearly in their natural state. With respect to the origin of pharmaceutical chemistry, it may be sufficient to observe that a rude species of chemical manipulation appears to have been practised in Arabia in the fifth century, that distillation was performed, and that the metals were subjected to various processes, by which some of their oxides and salts were produced. The immediate object of these processes was the transmutation of the metals; an operation which, for many centuries, formed a main subject of attention to almost all the individuals who were considered as cultivators of natural philosophy.

With respect to the second subject alluded to above, the description of new diseases, it is well known, that from causes which are now altogether inexplicable, diseases of the most marked and distinct nature, which are the least liable to be mistaken or confounded with other affections, and which, had they existed, are too violent to have been overlooked, are not mentioned by the Greek and Roman physicians, and are described for the first time by the Arabians. Of these the two most remarkable are the small-pox and the measles. There is some reason to suppose that the small-pox had been known in China and the more remote parts of India at a much earlier period, but it is generally admitted that it was first recognised in the western part of Asia, at the siege of Mecca,

* *Freind*, p. 503-6. *Bayle's* Dict., in loco. *Moreri's* Dict., in loco. *Haller*, lib. ii. sect. 142. *Eloy*, in loco. Nouveau Dict. Hist. in loco. *Enfield*, t. ii. p. 226-231. *Sprengel*, t. ii. p. 337-41.

about the middle of the sixth century, when it raged with great violence in the army of the besiegers. We have remarked above, that the disease was alluded to by Ahrun shortly after its appearance, but it was Rhazes to whom we are indebted for the first clear and distinct account of its symptoms and treatment. There is no subject in the whole range of medical science of more difficult solution than that which respects the origin of diseases, especially such as, when produced, are propagated solely by contagion. Into this subject, however, it would be improper for us to enter in this place, as our readers will find it fully considered in the appropriate articles; it is here only alluded to as an historical fact, in connection with the writings of the Arabians.*

We are indebted to them for the transmission of the works of the ancient Greek physicians, to which they made certain additions of insulated facts with respect to the description of diseases, but with respect to the general principles of therapeutics the additions, if any, were few and imperfect. In anatomy they made no advances, and we have reason to suppose that the examination of bodies, either in a sound or morbid state, was scarcely practised by them. Medical theory was much attended to, but their theories consisted more in subtile refinements, formed upon the Aristotelian model, than in the study of pathology, or an accurate discrimination of the phenomena of discase. Some little advance appears to have been made in surgery by Albucasis, but he is the only individual who seems to have aimed at improving this branch of the profession; and it may be doubted whether the practice of surgery was not, upon the whole, in a retrograde state, during the period of which we are now treating. It is in the department of pharmacy alone that they made any additions of real value; and, although in this case it may be attributed more to accidental circumstances than to any enlightened spirit of improvement, yet it is incumbent upon us to acknowledge the obligation, which was both extensive and permanent.†

CHAPTER VII.—*State of medicine in Europe after the extinction of the Arabian school—Medical schools of Monte-Cassino and Salerno—Medicina Salernitana—Constantinus Africanus—Actuarius—Rise of the study of anatomy—Mondini—Gilbert—Effect of the crusades, of the reformation, and of the invention of printing, on the literature of Europe—On medical science—Alchemists—Establishment of universities—Linacre—Chemical physicians—Paracelsus—Appearance of new diseases.*

During the flourishing period of the Saracenic school of medicine, which may be considered as extending from the eighth to the twelfth century, the science remained nearly stationary, or was even retrograde among the successors of the Greeks and Romans. We have scarcely a single name of sufficient importance to arrest our attention, and we have no improvements to record, either in theory or in practice. The only attempts that were made in Greece or in Italy during this period, which deserve to be noticed, are connected with the Neapolitan schools of Monte-Cassino and of Salerno, which acquired some degree of reputation in the eleventh century. It was at this period that the physicians attached to the school of Salerno wrote the verses on dietetic medicine, entitled "Medicina Salernitana,' a work which, as afterwards published with the commentary of Arnoldus de Villanova, acquired considerable celebrity, and may be regarded as a valuable document, by its affording, in a small compass, a correct idea of the state of Italian medicine at that early period.‡

In connection with this subject we may notice Constantinus Africanus, who is supposed to have flourished about the end of the eleventh century. He was, as his name imports, an African; he possessed an ardent desire to obtain knowledge, studied in the schools of Bagdat, and is said to have travelled even to India. At his return to his native country he was regarded as a sorcerer, and was compelled, in order to save his life, to take refuge in Italy, where he was finally attached to the university of Monte-Cassino. He principally employed himself in translating the works of the Greek and Latin physicians into Arabic, which was at that time the general language of science. His translations are, however, said to be incorrect, and his style barbarous; while his works, which are not professed translations, appear to be composed of transcripts from other authors, without any particular merit, either of selection or of arrangement. (*Freind*, p. 533, 4. *Haller*, Bibl. Med. lib. iii. sec. 159. *Eloy*, in loco. *Sprengel*, t. ii. p. 355, 6.)

We must mention in this place a writer whose real name has not been transmitted to us, commonly called Actuarius, from the office which he bore in the court of Constantinople; (for the origin of the term, see *Adelung*, Gloss. Man., in loco). He is supposed to have lived in the twelfth century. The works which he left are numerous, and, although consisting principally of extracts from Galen and the Arabian physicians, with whose writings he appears to have been familiar, are not without some additions derived from his own observations and experience. He is considered as having been the first Greek physician by whom chemical medicines are mentioned, as well as various articles of the materia medica, which were originally introduced by the Arabians. We may regard Actuarius as a diligent collector of

* On the origin of the small-pox, see *Freind*, p. 52-49; *Mead's* Discourse on Small-Pox and Measles, ch. i.; *Thompson's* Enquiry into the Origin of Small-Pox; *Plouquet*, Literatura Digesta, "Variola, Antiquitas, Historia," in loco: ample references may be found in this learned and laborious compilation on all analogous topics, but we may regret that the writer appears to have aimed rather at multiplying his authorities than estimating their value.

† We are indebted to Freind for a candid and judicious account of the Arabian medical school, p. 529-33. *Haller's* second book of his Bibl. Med. Prac. is devoted to the same subject. See also *Robertson's* Charles V. vol. i. note 28. *Berrington's* Middle Ages, App. No. 2. *Gibbon's* History, vol. x. ch. lii. *Ackermann*, cap. xxvii-xxix. *Oelsner*, Des Effets de la Religion de Mahommed, p. 196-9; this is perhaps too much disposed to exalt the merits of the Arabian school. *Kühn*, Bib. Med. sec. 3. of what he styles "Fontes Medicinæ," is entitled, "Scriptores Medici inter Arabes præcipui," p. 180-6. *Portal*, Hist. Anat. ch. ix. 'Des Anatomistes et des Chirurgiens "Arabes."

‡ *Haller* ascribes the Latin verses of the Medicina Salernitana to John of Milan; he remarks that of this work there had been published "editiones ferè innumerabiles;" Bib. Med. lib iii. sec. 140. See also *Eloy* t. ii. p. 599; *Ackermann*, sec. 422, and *Blumenbach*, sec. 114

facts, acquainted with all the information of his age, and as more free from prejudice and bigotry than the generality of his contemporaries. (*Freind*, p. 452–462. *Eloy*, in loco. *Sprengel*, t. ii. p. 241–4.)

After the extinction of the Saracenic school of Spain, we have an interval of about three hundred years, from the twelfth to the fifteenth century, during which what are termed the dark ages still remain enveloped in the deepest gloom; every department of science was neglected, and among others that of medicine fell into its lowest state of degradation. What remained, either of literature or of science was in possession of the monks, who were themselves grossly ignorant, and whose interest it was to preserve mankind in the same state of ignorance. The exercise of the medical profession was principally in their hands, and they still adhered for the most part to the doctrines and practice of Galen, but with these they mixed up a large portion of superstition, and had not unfrequently recourse to magic and astrology. By these means they obtained an unbounded influence over the minds of the people, and operated so powerfully on the imagination of their patients, as in many cases to give an apparent sanction to their confident assumption of supernatural agency.—(*Sprengel*, sec. vii. ch. i.) The only branch of science which was cultivated with any ardour or success, was chemistry. The chemistry of these times can indeed only be interesting to us, as having led indirectly to the discovery of various substances which have been found of great importance in medicine, to which we have already referred. Its immediate objects were two-fold, the transmutation of the baser metals into gold, and the discovery of what was termed a universal medicine, which should possess the property of removing all diseases, and preserve the constitution in a state of health and vigour; objects which it is unnecessary to observe were completely vain and illusory. Yet by promoting a spirit of research, and by making the experimentalist acquainted with the various forms and properties of the substances on which he operated, they gave him some insight into the physical laws of matter, and by a gradual although very slow process, laid the foundation of the splendid improvements of modern science. Many of the alchemists of the dark ages, we can have no doubt, were impostors of the lowest description, who were completely aware of the folly of their pretensions; but at the same time there were others who appear to have been the dupes of their own credulity, and who bestowed a large portion of their time and fortune upon these researches. Between these two extremes there were some rare cases of individuals who may be entitled to hold an intermediate rank, who were sincere and honourable in their views, and without giving full credit to the professions of the alchemists, conceived that the objects at which they aimed were at least not altogether impossible. To these we may add another class of individuals, consisting of that singular and unaccountable compound of knavery and folly, which is not confined to the subject now under consideration, where it is extremely difficult to draw the line between these two qualities, or to decide which of them forms the predominant characteristic.

The school of Salerno, to which we have referred above, obtained a degree of celebrity from its local situation, this city being one of the great outlets from which the crusaders passed over from Europe to Asia in their expeditions to Palestine; and it was probably from this circumstance that Robert of Normandy stopped at Salerno, in order to be cured of a wound which he had received in the holy wars. It was on this occasion that the verses mentioned above, and which were addressed to him, were written. Upon the decline of the Saracenic universities of Spain, the only medical knowledge which remained was in Italy, where a few individuals, who were not of the ecclesiastical profession, continued to comment on Galen and Avicenna, and occasionally to deliver lectures; but we have a long dreary interval, in which there is nothing to arrest our attention, or to relieve the dull monotony of ignorance and superstition.

During this period the school of Salerno still retained its reputation, and was even favoured with especial privileges by the emperors; but its merits were probably rather comparative than absolute, for we do not find any improvements that emanated from it, nor any authors whose writings maintained their celebrity after the age in which they were produced. It is, however, in one respect deserving of our notice, as it appears to have been the earliest establishment in which what may be styled regular medical diplomas were granted to candidates, after they had passed through a prescribed course of study, and been subjected to certain examinations. The regulations are upon the whole judicious, and display a more enlightened and liberal spirit than might have been expected in that age, when the human mind was in so degraded a state. (*Freind*, p. 535–7. *Eloy*, art. "Salerne." *Lauth*, p. 291, 2. *Ackermann*, cap. xxxi.) The school of Salerno maintained its celebrity until the thirteenth century, when it was eclipsed by the general diffusion of medical science through Europe, and more particularly by the rising reputation of the universities of Bologna and Paris.

It was about this period that we may date the commencement of a practice which has eventually proved of the greatest importance to medical science in all its departments—the study of human anatomy. We have already had occasion to remark that the ancients, even in their most enlightened ages, seldom if ever ventured to examine the human subject, but were content to derive their knowledge of it from the dissection of animals which were supposed the most nearly to resemble it, making up the deficiencies by the casual examinations which were afforded them by accidents or diseases, and perhaps more frequently by supposed analogies, or rather by the efforts of the imagination. The individual to whom the credit is ascribed of having so far overcome vulgar prejudice as to have introduced this most important improvement into his art, is Mondini, a professor in the university of Bologna, who is said to have publicly dissected two female subjects about the year 1315, and who published an anatomical description of the human body, which appears to have had the rare merit of being drawn immediately from nature. This work deservedly obtained a high reputation: for three hundred

years it was considered as a standard performance, and was used as a text-book in the most celebrated of the Italian universities. Mondini is also entitled to the gratitude of posterity for having given a very early, if not the first example of anatomical plates; the figures were cut in wood, and although, as might be supposed, they were not executed with much elegance or delicacy, they are said to have been correct and expressive.*

About the same time with Mondini lived Gilbert, surnamed Anglicanus, a writer who must be considered as peculiarly interesting to us, from his being the earliest English physician whose name is sufficiently celebrated to entitle him to a place in the history of medicine. There has been much controversy respecting the date of his birth; but it appears the most probable that he flourished in the beginning of the fourteenth century. At this time medical science, as well as all other kinds of knowledge in this country, was in a state of the lowest degradation. There were no public means of instruction in any of the branches of natural philosophy. The light of science, which had dawned in the south of Europe, had not yet extended to the remote shores of Britain, and the learning of the age, which was confined to the monks, consisted entirely of scholastic disquisitions and the disputations of polemical theology. We are not therefore to expect, in the writings of Gilbert, much of genuine philosophy or of real science; his principal work, which is entitled "Medicinæ Compendium," consists chiefly of subtile distinctions, disquisitions respecting trifling and insignificant topics, with minute divisions of his subject, which lead to no useful purpose or general conclusion. His medical theories are principally taken from Galen, while his mode of reasoning proceeds upon the technical principles of the Aristotelian dialectics; he adopts the former without discrimination, and employs the latter without judgment. He frequently refers to the Arabian physicians, and there is some reason to suppose that it was through their means, *i. e.* through the medium of the Latin translations of their writings, that he made himself acquainted with the opinions of Galen. (*Wurton's* Hist. of Eng. Poet. v. i. p. 443.)

But although we are compelled to pass this general censure upon the works of Gilbert, justice demands it of us to admit that his defects may be fairly ascribed to the age and country in which he lived, and that he deserves great commendation for the attempt which he made, however imperfect it may have been. Nor are his works entirely without merit or originality; he has described some diseases in such a manner as to show that, under more favourable circumstances, he might have excelled in the art of making observations; he occasionally gives us some particulars of his practice, which prove that he was capable of exercising a correct judgment in the treatment of the cases which were submitted to him, and we are indebted to him for some additions to the materia medica, and for some improvements in pharmacy. (*Freind*, p. 547–50. *Eloy*, in loco. *Aikin's* Biog. Mem. of Med. in Gt. Brit. p. 8, 9. *Sprengel*, t. ii. p. 402–6.)

About this period, a grand political revolution was commencing in Europe, which eventually produced an entire change in the civil condition of its inhabitants, and indirectly affected, in an equal degree, its science and its literature. The feudal system, after being firmly established for some centuries, began to be shaken, perhaps in the first instance by the crusades. These expeditions, although undertaken from a spirit of gross superstition and bigotry, yet by giving a degree of excitement to the mind, and still more by making the crusaders in some degree acquainted with the literature of the Arabians, laid the foundation for subsequent improvements. There has been much controversy, not only respecting the absolute merit of the Arabian literature, but respecting the influence which it had on that of Europe. On the first of these points, so far at least as regards the medical sciences, we have already offered a few remarks; and on the latter we may observe that at the period of the crusades, whatever may be our estimate of the absolute merit of the Saracenic schools of learning, they were undoubtedly superior to those of the Christians, if indeed these latter can be entitled to the appellation. The armies of the crusaders were certainly not the best adapted either for appreciating the learning of the countries which they invaded, or for transferring any portion of it to their own; but still an intercourse of two or three centuries could not fail of having produced some effect, and in fact we know, not only that Arabian books were read and studied in Italy and France, but that it was almost exclusively by the medium of these books that the knowledge of the Greek and Roman authors was kept alive.†

The advantages which were derived to the Europeans from their intercourse with Asia, were, however, of but little moment compared to the great events to which we alluded above. The first of these was the capture of Constantinople, in the middle of the fifteenth century, by Mahomet the Second. The Greek monasteries of this city had been for some time the refuge of the learned men who had been driven from Italy by the perpetual wars in which that country had been so long engaged. They had taken with them, what they considered as their most precious treasures, the manuscripts of the ancient classical writers, probably regarding them more as objects of curiosity than of real importance. These manuscripts had now been buried for a long time in their libraries, their existence being unknown to the rest of the world, when the monks were expelled from their retreats by the Turkish conqueror, and, flying into Italy, carried back with them their classical manuscripts. A spirit of improvement had already begun to manifest itself in this country, which was considerably incited by their guests, who in their turn, by their change of situation and by the new society into which they

* *Freind*, p. 546. *Haller*, Bibl. Anat. sec. 120, t. i. p. 146, 7. *Eloy*, in loco. *Portal*, Hist. Anat. t. i. 209–16. *Sprengel*, t. ii. p. 432–4. *Douglas*, Bibliogr. Anat. p. 36–9. *Blumenbach*, sec. 118.

† *Gibbon*, ch. lxi. *Sprengel*, sect. 7, ch. iii. We must remark that the opinion expressed in the text respecting the influence of the crusades on the literature and science of Europe, differs in some degree from that of Mr. Mills, as stated in his interesting work on the Crusades, v. ii. p. 354–68.

were introduced, became more aware of the value of their literary treasures; while their own acquirements, limited as they were, gave them a degree of respect with their new associates which tended to inspire them with a desire of further improvement. (*Ackermann*, ch. xxxii. *Cabanis*, § 7.)

The other event to which we referred, and which occurred about thirty years after the destruction of the Byzantine empire, was one of infinitely more importance both in its immediate and its ultimate effects. Considered in all its bearings, both moral and political, it may probably be regarded as the most important which has ever occurred in the history of civilized society. Our readers will not need to be informed that the great event to which we refer is the Reformation. Into the causes of this event, the motives of Luther and his associates, the difficulties with which they had to struggle, and the means by which they succeeded in overcoming these difficulties, it is not our business to inquire. It only remains for us to notice its effects on science, and more particularly on medical science. We have remarked above that a certain degree of mental exertion had begun to manifest itself in the fourteenth century, that this was in some measure brought into action by the excitement produced in consequence of the crusades, and that the minds of men were thus prepared to receive the great truths which were so powerfully impressed upon them by the reformers. The first effect, however, of the Reformation was rather unfavourable to the progress of science and literature. The attention was entirely absorbed by the violence of theological controversy, and the civil feuds which succeeded put a stop to the peaceful labours of the scholar and the philosopher. But if a temporary pause was thus produced, the subsequent advance was proportionally rapid. No sooner were the minds of men delivered from the thraldom of theological bigotry, than they felt a strong impulse to free themselves from the tyranny of opinions on all other subjects in philosophy; and although it still required the lapse of some centuries to shake off the undue authority of Aristotle and Galen, and to form a fair estimate of their real merits, they were at least regarded as fair topics for discussion, while innovators were every day rising up who ventured to question their infallibility without the danger of being stigmatized as schismatics and heretics. (*Enfield*, v. ii. book 8, ch. ii.)

The happy invention of the art of printing, "an art which derides the havoc of time and barbarism," and which fortunately occurred about the same period, most powerfully tended to co-operate with the labours of the reformers, both in religion and in science, by affording them the means of more readily communicating the result of their inquiries, and of preserving the records of knowledge from the danger which they had lately experienced of being totally lost or destroyed.* One of the first uses which was made of this important invention was not only the multiplication of the works of the ancient classics, which had been brought by the Byzantine monks into Europe, but, by making mankind sensible of their value, other works of a similar kind were eagerly sought after, and thus, in the course of a few years, manuscripts were discovered of almost all the classical writings of which we are now in possession. (*Gibbon*, v. x. ch. lxvi. *Warton*, passim. *Berington*, book vi. p. 478 et seq. *Shepherd's* Life of Poggio, passim. *Hallam's* Middle Ages, v. iii. p. 577 et seq.) The munificence, and even the voluptuous extravagance of Leo X. and the other Italian potentates, by the direct encouragement which they gave to literature and the fine arts, powerfully coincided with the current of public opinion. For although, by inciting the daring spirit of Luther to take those steps of open hostility against the papal authority which he probably little contemplated in the first instance, they produced effects very different from those originally intended, yet they must be considered as among the indirect causes which conspired to produce the great mental revolution of the fifteenth century.

The science of medicine in its various departments was not slow in partaking of the beneficial effects of the change which we have been describing. The writings of the Greek physicians, which had for some centuries been studied through the medium of Arabic translations, or even of Arabic commentaries, were now read in their original language or in correct Latin versions. It was found that Avicenna, Averroes, and the great luminaries of the Saracenic schools, had in many cases either misunderstood or perverted the doctrines and tenets of Galen, and his genuine writings now began to be substituted for the imperfect transcripts of them which had so long occupied their place. The works of Hippocrates were also printed in their original form; but it required a considerably longer period of mental education to enable the bulk of medical readers to appreciate his merits, so that, although various editions of his works were printed, and learned treatises written to explain them, Galen still retained the pre-eminence in public estimation.

A practice began to prevail about the fifteenth century which very materially contributed to advance the science of medicine, and especially the practical part of it,—the publication of monographs of particular diseases and of individual cases, with the reports of hospitals or other public institutions. This plan was not, indeed, altogether new, for we meet with narratives of cases even in Hippocrates; but it had been either misunderstood, or had been so much perverted from its original design and legitimate object as to have been rendered of little value. Many of these early collections, it must be acknowledged, were formed without judgment, and consisted rather of marvellous stories than of histories from which any practical inference could be deduced; but they served the purpose of inducing a habit of observation, and of directing the attention more to facts than to mere hypotheses. In each succeeding age we find this plan to have been more generally adopted, and at the same time to have been much improved in its method; so that we may undoubtedly consider it as one of the means by which medical knowledge has advanced so rapidly in modern times.

* For remarks on the scarcity and value of books, see Robertson's Charles V., v. I. ch. v. note 10; Warton's Hist. of English Poetry, passim; Berrington's Middle Ages, book vi. p. 507, 8.

Before we close our second period of the history of medicine, it will be necessary to make a few observations on the progress of chemistry, and on the influence which it had on medical science. We have already made some remarks on the rise of this science, and on the progress which it made among the Arabians, and have stated that it originated in the futile and sordid desire of converting the baser metals into gold. In its primary object it of course totally failed; yet in the numerous and laboured efforts which the alchemists made to accomplish their object, it is admitted that they acquired considerable information about the nature and properties of the bodies on which they operated, and thus produced various compounds, principally of a metallic nature, which were eminently useful in the arts of life, and especially in pharmacy. We farther owe to the Arabian chemists the discovery of the process of distillation, the art of preparing extracts; they introduced the use of sugar into pharmacy instead of honey in the composition of syrups and conserves: they seem to have made some approach to the formation of the mineral acids, and to have procured several of the earthy and neutral salts.

The art of alchemy was early transferred into the different countries of Europe, and was pursued with as much ardour as by the Arabians, and perhaps with even more superstition and credulity. Some of the alchemists acquired, during their lifetime, a high degree of popularity, and notwithstanding the unphilosophical nature of their occupation, are not altogether unworthy of notice in the history of science. Albertus Magnus, bishop of Ratisbon; Raymond Lully, a Spanish ecclesiastic; and Arnoldus of Villanova, a professor in the university of Barcelona, all flourished in the thirteenth century, and left behind them writings which, although they are encumbered with a mass of folly and mysticism, exhibit, in a certain degree, the spirit of philosophical research, together with an ample share of industry and patient investigation.* In the same age lived Roger Bacon: he may be classed among the alchemists, inasmuch as he adopted some of their principles and practices; but in the turn of his mind, and in the spirit with which he entered upon his experimental researches, he exhibited a genius which far outstripped the age in which he lived.† The philosopher's stone, which was the object of so much painful research, besides its property of producing gold, was supposed also to possess the power of curing all diseases, and hence obtained the title of the universal medicine. This vain and fantastical notion was indirectly the cause of some pharmaceutical discoveries; for to this we may consider ourselves indebted for the mercurial preparations, and for the experiments of Basil Valentine on antimony, which led to their introduction into medicine about the end of the fourteenth century.

Among the distinguishing features of the period at which we are now arrived, we must not omit to mention the various universities which were established in most of the great cities in the southern parts of Europe, of which the medical chairs, in most cases, formed a very distinguished part. We have already had occasion to mention the university of Salerno, which was the first of these establishments after the destruction of the Roman empire. The next in order of time appears to have been that of Montpellier, which is said to have been established not long after that of Salerno, and which acquired a high degree of reputation, which it maintained for many centuries. We are informed that Bologna had acquired considerable celebrity as a school of medicine in the thirteenth century; that about half a century later, medical lectures were delivered in the universities of Vienna and Paris; and that about the same time, medical schools were established in Padua, Pavia, Milan, Rome, and Naples, and most of the other cities of Italy, which each of them acquired a certain degree of reputation, necessarily varying with the abilities and characters of their professors, but all contributing to advance medical science, both by the actual acquisition of knowledge, and by the influence which they exercised in removing the undue veneration that was still paid to the writers of antiquity.‡ In the north of Europe, the progress of literature and science was much more tardy. The natural sciences were scarcely regarded as an object of attention, and medicine was still strictly confined to the study of the works of Galen, or even to those of his Arabic translators. The only exception of which our country can boast, is Linacre, a native of Canterbury, who, after studying at Oxford, travelled into Italy, and spent some time at the court of Florence, where he acquired a portion of that love of literature which so eminently distinguished the family of the Medici. On his return to England, he was appointed physician to the royal household, and employed his influence in establishing medical professorships in the universities of Oxford and Cambridge, and in forming the foundation of the London College of Physicians.§

From the various causes which we have mentioned, and probably from some others of less moment, a spirit of general improvement now began to manifest itself; the arts and sciences gradually revived; philosophy, in all its branches, was studied on a more correct plan and with a more enlightened object, and medicine was not slow in

§ *Freind*, p. 587-591. We here lose the assistance of this learned and judicious historian. *Eloy* in loco. *Cabanis*, p. 144, 5. *Sprengel*, t. ii. p. 8. *Aikin's* Biog. Mem. of Med. p. 28-47. In connection with Linacre, we may mention the name of Key, Kays, or, as it was Latinized, according to the custom of the times, Caius, whose liberality to the university of Cambridge deserves honourable mention. *Aikin*, in Biog. Anec. p. 103-136; and in Gen. Biog., in loco. *Eloy*, in loco.

partaking of the beneficial influence. One of the first symptoms of this improvement was an increasing relish for the writings of Hippocrates, and the revival of his method of studying and practising medicine. The taste for complicated theory and refined speculation gradually declined, and in the same proportion the value of correct observation and an accurate detail of facts began to be duly estimated.

A circumstance which tended in a considerable degree to shake the authority of Galen, and to diminish the veneration in which his opinions had been held for so many ages, was the rise of the sect of the Chemical Physicians. After chemistry had been used with advantage for the purpose of improving the processes of pharmacy, it was applied to the explanation of the phenomena of vitality, and of the operation of morbid causes upon the living system. The theories of these chemical physicians we now regard as altogether false and inapplicable; but they were advanced with so much confidence that they obtained many adherents, and for some time the opinions of the medical world were divided between the rival doctrines of the Galenists and the Chemists.

Among the most noted supporters of the chemical theory was Paracelsus, an individual whose claim to our notice depends more upon his consummate vanity and presumption than upon his abilities or acquirements. His professed object was to undermine the authority of the Galenists; and for this purpose he did not hesitate to hold forth the most absurd claims, and to practise the basest acts of quackery. He boasted that he had discovered the elixir vitæ, the universal remedy, of which mankind had been so long in search; and he publicly burned the writings of Galen and Avicenna, because, in consequence of his discovery, they were of no further use. It is somewhat difficult to determine in what degree Paracelsus was actually the dupe of his own folly; but whatever may have been his real opinion as to the efficacy of his elixir, his own death, at the early age of forty-eight, served to humble the confidence of his followers, and to reduce his reputation to its real standard.

But although the personal character of Paracelsus received an irreparable shock by this event, his doctrines continued to attract a number of zealous advocates. With respect to the nature of these doctrines, it will be necessary for us to say but a few words in this place. The leading principle of the Chemists was, that the living body is subject to the same chemical laws with inanimate matter, and that all the phenomena of vitality may be explained by the operation of these laws. The proofs which they adduced in favour of this principle, and the illustrations which they gave of the nature of these laws, were completely futile and unsatisfactory; and it may be asserted that the strength of their reasoning was much more apparent in the mode by which they attempted to controvert the hypothesis of the Galenists than in the direct arguments which they brought forward in favour of their own doctrine. In truth, the chemical elements of Paracelsus were at least as hypothetical as the physiological elements of Galen, and were even less applicable to the explanation of the vital actions of organized beings. The only obligation which we owe to the chemical physicians, is the introduction into medicine of certain substances, chiefly metallic preparations, which, in the hands of the more enlightened practitioners of modern times, have proved very valuable additions to the materia medica.*

After the death of Paracelsus, his peculiar theories fell into disrepute and were little attended to; but the sect of the Chemical Physicians continued to flourish even as late as the seventeenth century, when we meet with many examples of men of learning and sagacity, who attempted to explain the phenomena of the animal economy by the laws of chemistry. To the visionary speculations of the Chemists there was united a large portion of superstition and mysticism; and so much did this feeling coincide with the spirit of the times, that even the men who were the most illustrious for their learning and science were either actually infected with these notions, or did not venture so far to oppose the prevailing opinions of their contemporaries as to avow their disbelief of them. Astrology and magic were generally practised by the members of the medical profession, while various rites and ceremonies were observed, which implied the belief of supernatural agency, but which, by a singular inconsistency, was supposed to be a constant and necessary part of the process.

Before we conclude this portion of our subject, we must notice the remarkable circumstance, that about this period, during the fourteenth and fifteenth centuries, some very formidable diseases made their appearance in Europe, the origin of which is still very obscure, after all the discussion and investigation that has taken place respecting them. Among these, one of the most remarkable is what was termed the *sudor Anglicanus*, which is first mentioned about the end of the fifteenth century, and which, for about fifty years, raged at intervals with extreme violence in England and in some other countries in the west of Europe. (*Sennert*, De Feb. lib. iv. cap. 15. *Freind*, p. 567, 8. *Plouquet*, "Febris Sudatoria," t. ii. p. 162. *Cullen's* Synopsis, t. ii. p. 77, 8. *Sprengel*, t. ii. p. 491-4.) In the fifteenth century we have the first correct description of the hooping-cough; and from the manner in which it is spoken of by the contemporary writers, it would appear that it was considered by them as a new disease. The sea-scurvy, if not entirely unknown to the ancients, was at least not distinctly recognised until this period, so that, if it existed previously, we may conclude that it was less violent in its effects; a circumstance which has been ascribed, with great plausibility, to the spirit of naval enterprise which sprang up at this period, and which led to the undertaking of long voyages. (*Freind*, p. 583. *Sprengel*, t. ii. p. 494-6.)

The great number of establishments which were formed during the dark ages for the cure of leprosy, was at one time supposed to be a proof

* *Clerc*, p. 792 et seq. *Barchusen*, Diss. 19. *Conring*, cap. xi. sec. 16, 17. *Haller*, Bib. Med. t. ii. p. 2 et seq. *Eloy*, in loco. *Sprengel*, sect. ix. ch. 2. *Gabanis*, sect. ix. *Hutchinson's* Biog. Med. vol. ii. p. 197-209. *Enfield*, vol. ii. p. 451-4. *Aikin's* Gen. Biog., in loco. *Blumenbach*, Introd. sect. 169. *Renauldin*, in Biog. Univ. "Paracelse."

that it was a new disease in Europe, imported, as was imagined, from Asia by the crusaders. There has been much nosological discussion concerning the exact nature of the disease to which this term ought to be applied; whether there were actually two species of leprosy, one which was indigenous in the east, and another species in Europe. Some writers have conceived that a combination of the two was produced at this period, while others, again, have supposed that the disease had previously existed in Europe, but that, in consequence of the greater degree of communication between the different parts of it which was brought about by the crusades, the disease was either more extensively propagated, or at least was brought more into notice, and that more active means were therefore employed for its relief. (*Sprengel*, t. ii. p. 371-5.)

It was about the same period, when the western part of the old continent was in its lowest state of degradation, that we hear of the ravages of those varieties of fever emphatically styled the plague, which were described in the thirteenth, fourteenth, and fifteenth centuries as invading various parts of Europe and Asia, and sweeping away a large proportion of the inhabitants. (*Plouquet*, "Febris Maligna," and "Pestis," in loco. *Cullen*, t. ii. p. 74-7, 139-41.) The accounts which we have of these epidemics would indicate that they were not an absolutely new disease, but that the symptoms were modified and aggravated by the peculiar condition of the great bulk of the people; a conclusion which is confirmed by the fact, that, as the physical and moral condition of nations has been ameliorated, the occurrence of these diseases has become proportionally rare, so that we conceive them to be almost incompatible with the improvements in civilization and in medical police which exist in the greatest part of Europe.

But whatever may be our opinion concerning the origin of the leprosy and the plague, there is another disease where, from the peculiarity of its symptoms, its decidedly contagious nature, the ordinary method of its propagation, and the universality of its occurrence, we are enabled to fix the date of its appearance in Europe with more certainty. It is now generally agreed that it was near the close of the fifteenth century that the symptoms of syphilis were first recognised in Italy, from which country the disease very rapidly extended over the whole of Europe. Concerning its primary origin much controversy has taken place; many writers have attempted to prove that it was brought into Europe from America by Columbus; but this opinion, which was at one time pretty generally received, is now abandoned, nor are we able to offer any plausible conjecture respecting its introduction from any other quarter.

The same difficulty indeed exists in this case as in that of all those diseases which are produced by no cause except by a specific contagion. Almost every individual is obnoxious to them upon the application of this cause, and this liability appears to be little affected by constitution, age, habits of life, climate, and other external circumstances. The question is, how were they first produced? It is impossible to imagine that the first created individual was born with all these diseases upon him, yet we know of no distinct cause now in operation which could, in the first instance, have generated them. These remarks apply to the small-pox and the measles, which, as was stated above, were first known to the Europeans about the middle of the sixth century, and it applies perhaps, still more remarkably to the case of syphilis. This point must be regarded as one of those mysteries of which at present we are unable to offer any solution. It is true that the manners of the age in which this disease is recorded to have first made its appearance were grossly licentious, and in many respects unfavourable to health; but still we see no satisfactory reason why the specific poison of this disease should have been generated; yet it appears impossible to conceive that, if it had previously existed, it could have remained for any length of time unknown or undescribed.*

We have now brought down our sketch of the history of medicine to the period when the light of improvement was bursting forth from various quarters, when men were engaged in the investigation of the different departments of science upon a plan which, although not free from error, was more correct than that of their predecessors, and which by a slow but steady process led to the establishment of those principles which eventually produced the complete triumph of truth and philosophy over error and superstition.

CHAPTER VIII.—*General view of the state of medicine during the sixteenth century—Revival of the Hippocratean school—Account of the Galenists—The Chemists—The Anatomists—Vesalius, Fallopius, Eustachius.*

We have already given an account of the manner in which the taste for the classical writers of antiquity was gradually developed during the fifteenth century, and we stated that in medicine, as well as in the other departments of science, the Greek writers began to be studied in the original instead of their being read through the medium of translations and commentaries. As this taste was further matured, the works of Hippocrates continued to rise into estimation in preference to those of Galen, and a new school of medicine was formed, which obtained the name of Hippocratean, the professed object of which was to proceed upon the inductive principle, of first ascertaining facts, and by their generalization to form the theory. That in every instance they adhered to this plan we cannot affirm; indeed we have too many instances where they forgot or misapplied their own principles, but still the importance of accurate observation was generally admitted, and although mankind could not at once abandon their former errors, they became aware of their existence, and of the method by which they might be corrected.

The contest between the Galenists and the Chemists, which agitated the whole medical world during the fifteenth century, was indeed still maintained through the sixteenth; but it was conducted upon more rational principles, and by men of more enlarged and more enlightened views.

* *Freind*, p. 568-583. *Astruc.* De Morbis Veneriis. *Hunter.* on the Ven. Dis. p. 9. 10. *Sprengel*, t. ii. p. 499 et seq. *Plouquet*, "Syphilis, Historia" &c. in loco. *Black's* Hist. of Medicine, p. 146-155.

The Galenists were for the most part more scientific and learned than their adversaries; they consisted of the professors in the universities, and what may be styled the regular practitioners; and although they were still strongly attached to the tenets of their master, they did not omit to collect facts and to watch the phenomena of disease. Their practice may be characterized as being at the same time complicated and inert; their materia medica was principally taken from the vegetable kingdom, while their prescriptions were long and multifarious, consisting of a prodigious number of articles, combined together in such a manner as to render it almost impossible to conceive the probable operation of the compound, their indications at the same time being derived from an incorrect hypothesis, and being often either unintelligible or impracticable.

The Chemists were the bold empirics of the day, without learning or experience; but they endeavoured to supply the deficiency by confidence and temerity, and by these formidable weapons they frequently triumphed over their adversaries. They discarded the long prescriptions of the Galenists, rejected many of the articles of their pharmacopœia, while they introduced the active metallic preparations, and made free use of the most powerful remedies of all kinds. The rival sects mutually upbraided each other with the injurious effect of their respective plans of treatment, and probably there was but too much foundation for their accusations; for if on the one hand the Chemists, by their rashness, committed many fatal blunders, the Galenists, by their feeble remedies, must have frequently failed in subduing disease or arresting its progress.

It appears that upon the whole the Chemists, like the analogous characters in the present day, acquired a greater share of popularity than their opponents. Their arrogant pretensions, the more decisive and intelligible nature of their indications, coupled with the artifices which they practised for the mere purpose of acquiring popularity, gave them a decided advantage over their more learned and more dignified rivals, who were both unable and unwilling to contend with them in the race of empiricism. By degrees, however, the chemical physicians rendered themselves more worthy of the public estimation, by making themselves better acquainted with the principles and practice of their art; the search after the philosopher's stone was gradually abandoned; and although many of the doctrines which they still professed were altogether unfounded, they were less palpably absurd than those of their predecessors.

Another circumstance occurred about the period of which we are now treating, which contributed to produce a most important reform in the science of medicine — we refer to the study of human anatomy. With a very few exceptions, which have been noticed above, during a space of more than a thousand years, since the death of Galen, very little advance had been made in our acquaintance with the structure of the body. The professors of the Arabian school, with their successors in Italy and France, for the most part contented themselves with copying the descriptions of the ancients, without ever calling in question their accuracy, or endeavouring to confirm or refute them by their own observations. Even after the examination of the human subject had been practised for some time, and its necessity generally acknowledged, it was long before mankind could so far free themselves from the tyranny of authority as to admit that any imperfection could exist in the works of Galen, or that his descriptions were not to be preferred even to the evidence of the senses.

In reviewing the state of medical science during the sixteenth century, it will assist us in our progress if we arrange the principal authors under the three classes of the Physicians strictly so called, the Chemists, and the Anatomists. Under the first head we propose to include both the writers who still adhered implicitly to the tenets of Galen, and those who, paying less regard to mere authority, devoted themselves more to observing the phenomena of disease and the effects of remedies, and who may be considered as having laid the foundation of the modern Hippocratean school. Of these, some of the most distinguished by their character or writings were Cornarus and Mercurialis in Italy, Hollerius, Fernel, and Duret in France, Lommius and Forest in Holland, Sennert, Plater, and Foës in Germany, and Linacre in England. (*Sprengel*, t. ii. passim. *Cabanis*, ch. ii. § 10.)

The limits to which we are confined will not permit us to enter into any detail of the individual merits of these authors, or into any analysis of their writings or opinions. For the most part they were possessed of a competent knowledge of ancient literature, and well acquainted with the works of the Greek physicians; many of them were professors in universities or teachers of medicine, and engaged in extensive practice. They were generally diligent collectors of facts, and many of them voluminous writers, either publishing their own observations, or commenting on the ancients. Their practice was in a great measure taken from Galen, with the additions that had been derived from the materia medica of the Arabians, and in a few instances from the Chemists; but these latter were regarded as dangerous and empirical, and it was not until they had been long sanctioned by popular use that they were received into the authorized pharmacopœias. The actual advance which the practice of medicine received from these authors was not very considerable; but by their learning and diligence and their general respectability they contributed to raise the character of the profession, and to prepare the mind to receive the improvements in science which were gradually unfolded in the next century, and to apply them to the department of medicine.

With respect to the Chemists of this period, although they composed a numerous and active body, yet there is none of them whose name is sufficiently distinguished above his fellows to require being particularized in this place. As science and knowledge gradually advanced, the absurdity of their speculations was more generally perceived, and their pursuits were either abandoned, or were directed by a more philosophical spirit; and although the search after the universal medicine was not entirely discarded, they began to occupy themselves with inquiring into the chemical constitution of the body, and investiga

ting the changes that were induced in it by disease. This investigation was indeed attended with little success; their experiments were crude and imperfect, and their modes of analysis altogether inefficient. But still some important observations were made, and new processes were invented, and the foundation began to be laid for the more enlightened views of their successors in the succeeding century.

But the benefit conferred upon the science of medicine by the labours of the Chemists was trifling and uncertain compared to the great and direct advance which was produced by the researches of the Anatomists. Some attention had been paid to the structure of the body by the earlier Italians, and they had even ventured, in a few instances, to dissect the human subject; yet scarcely any discovery or any improvement deserving of notice had been made for many ages, when Vesalius, about the middle of the sixteenth century, entered upon his career of inquiry. He was the first anatomist who threw off the yoke of authority which had been imposed by a blind veneration for the opinion of the ancients, and who ventured to conceive the possibility of error in the writings of Galen. Vesalius prosecuted his researches with unwearied diligence, and disregarding the obloquy which was heaped upon him, he succeeded in publishing an anatomical work, which at this day we behold with admiration, and which maintains its character as a faithful transcript of nature. (*Eloy*, "Vésale." *Haller*, Bib. Anat. lib. 4, § 163. t. i. p. 180 et seq. *Sprengel*, t. iv. p. 5-9; *Douglas*, Bibliogr. Anat. p. 64-73. *Renauldin*, in Biog. Univ. "Vésale.")

But the reputation of Galen was too firmly established to be affected in any considerable degree by the observations of any single individual, however highly he might be entitled to the respect of his contemporaries. Long and acrimonious discussions occurred between the defenders and the opposers of Galen, some maintaining that his descriptions of the parts of the body were absolutely perfect, while others undertook to prove, by direct and palpable facts, that Galen's knowledge of the human form was not complete. It was asserted, on the one hand, that he had seldom examined the human subject, and that his descriptions were frequently taken from apes and monkeys; an imputation which was firmly denied by his zealous advocates. Eustachius, Fallopius, and others of great and deserved reputation for their anatomical skill, undertook the defence of Galen; and it was not until after a long and severe struggle that the truth was established, and that it was agreed that the anatomy of the ancients was in many parts imperfect, and that the errors which had been pointed out by Vesalius actually existed.* It would be foreign to our purpose to enter into a minute examination of the labours of the individual anatomists, or to mention in detail the successive improvements which were effected in their department. With respect to the practice of medicine, which is our more immediate object, it does not appear that they effected any direct improvement, but they contributed indirectly to its advancement in no small degree by completely establishing the important point that the opinions of the ancients were not to be considered as infallible, but were to be subjected to the ordeal of free inquiry.

CHAPTER IX.—*State of medicine during the seventeenth century—The chemical and mathematical sects—Progress of anatomy—Fanatics—Chemical physicians—Sylvius—Willis—Sydenham—Mathematical physicians.*

All the changes of opinion which we have described as occurring in the sixteenth century continued to advance with an accelerated progress during the seventeenth. The preference which was given to Hippocrates over Galen was daily gaining ground, and, as the consequence of this, the habit of correct observation was confirmed, and the value of the observations was more justly appreciated.

In the mean time, anatomy was making rapid strides. Being a science which depended more immediately upon the accumulation of matters of fact, which required for their attainment little more than industry and mere observation, errors were more readily discarded than on those subjects in which much reasoning was necessary, and in which it was rather an inference from facts than the facts themselves, which constituted the object of the investigation. The investigations of the anatomists extended to every part and structure of the body; the forms and textures of the bones, the muscles, the nerves, the vessels, and the various viscera, were each in their turn made the subject of particular and minute examination by some of the eminent men of the age. These labours were amply rewarded by the splendid discovery of the circulation by the immortal Harvey, and of the absorbent system by Asselli, Rudbeck, and Bartholine; while the structure and office of the lungs, and the relation which it bears to the heart, were explained by Malpighi, Hooke, Mayow, and their associates.†

With respect to the chemists of this period, their opinions were gradually disengaged from the tissue of mystery and credulity in which they had been so long involved, when about the middle of the century the science was finally placed upon its correct philosophical basis by the genius of Boyle. He correctly regarded it as an investigation into the change of properties which bodies experience by their action upon each other, and he pursued the investigation, not by presupposing the existence of certain occult causes and hypothetical agencies, but by an accurate examination of the effects which bodies actually produce upon each other when placed within the sphere of their mutual action.‡

It is, however, not a little remarkable that while the science of chemistry generally, and more especially the sect of the Chemical Physicians, was purifying itself of its grosser errors, we meet with not unfrequent instances where it continued to be

combined with a singular degree of fanaticism. There was indeed no period, since the time of Paracelsus, when there were more remarkable examples of the prevalence of this spirit, and in no country were they more notorious than in England. The writings of Fludd, who practised in London in the early part of the seventeenth century, afford a curious compound of learning and folly, of profound erudition, united to an implicit faith in astrology, and in all the cabalistic opinions of the Jewish doctors.* Perhaps a still more remarkable example of this combination is that of the celebrated Kenelm Digby, a man of rank and of refined education, who during his travels on the continent became initiated into this mysterious chemical philosophy, and on his return gave a specimen of his opinions by publishing an account of the virtues of the sympathetic powder.† Another of these individuals who obtained great celebrity was Valentine Greatrix, who cured all diseases by the imposition of the hand, and who even ventured to oppose his power in this respect to the royal touch of Charles.‡ These circumstances are interesting, not merely as forming a part of the history of medicine, but as displaying a singular feature in the history of the human mind; demonstrating the difficulty which exists in eradicating from it errors and follies even the most gross and palpable, when they have once become deeply rooted.§

While what may be more strictly termed chemistry was advancing into the state of a science, a combination was formed between its principles and those of physiology, which gave rise to the new sect of the Chemical Physicians. Their leading doctrine was, that the operations of the living body are all guided by chemical actions, of which one of the most important and the most universal is fermentation. The states of health and of disease were supposed to be ultimately referable to certain fermentations, which took place in the blood or other fluids, while these fluids themselves were the result of specific fermentations, by which they were elaborated from the elements of which the body is composed. Again, certain humours were supposed to be naturally acid, and others naturally alkaline, and according as one or the other of these predominated, so certain specific diseases were the result, which were to be removed by the exhibition of remedies of an opposite nature to that of the disease in question. According to the theory of the Chemical Physicians, fever was supposed to originate in an acid condition of the humours, and was consequently to be cured by alkalies; and in conformity with what is so often found to take place in tracing the history of medicine, they discovered that alkalies were actually the most efficacious remedies for fever.

The individual who may be considered as having first given a connected and consistent view of the theory of the medical chemists, is Sylvius. He was born at Hanau, in Flanders, in 1614; he graduated in the university of Basil, practised for some time at Amsterdam, and finally was appointed to fill the chair of practical medicine at Leyden, where, by his genius and eloquence, he acquired a high degree of popularity. From this circumstance, his peculiar opinions obtained a very extensive circulation, and the hypothesis of fermentation, with the acid and alkaline states of the fluids, after some time became the fashionable doctrine of the French and German physicians, and had many zealous defenders in our own country.‖

One of the most respectable of the advocates of the chemical doctrines of medicine, was our learned countryman Willis. He was only a few years younger than Sylvius, and was early in life attached to the science of chemistry, which he afterwards applied with much ingenuity to the explanation of the functions of the animal economy. In the year 1659 he published his celebrated treatise on fermentation and on fever, the object of which is to prove that every organ of the body has its peculiar and appropriate fermentation, and that a morbid state of these ferments is the cause of all diseases. The hypothesis is in itself totally false, but it is supported by considerable ingenuity, and his works are of real value, as containing an accurate account of the phenomena of disease. Willis was also the author of some treatises of very considerable merit on the nervous system, and on various physiological topics, by which his reputation is amply supported as one of the most eminent medical philosophers of the age.¶

The reputation of Willis has, however, been somewhat obscured by the still higher reputation of Sydenham, a man scarcely inferior to any that has passed under our review. He has been frequently styled the English Hippocrates, and there are various points of analogy between them, both as to general character and as to their peculiar mode of viewing the operations of the animal frame. The writings of Sydenham, like those of his great predecessor, abound in theory, but they also resemble those of Hippocrates, in containing the most accurate detail of facts, indicative of a mind of great sagacity, which enabled him to seize upon the most essential features of a disease, and to direct his attention to those points alone which tended to illustrate the nature of the morbid changes that were produced. But the great merit of Sydenham, that which has raised his reputation to so high a pitch of celebrity, and which causes his works to be still read with admiration, is the same with that which was ascribed to Hippocrates, viz. not allowing his speculative opinions respecting the nature or cause of diseases to interfere with the treatment. He carefully observed the operation of remedies on the symptoms, and

the action of the various external circumstances to which the patient is exposed, and from their effect he deduced his indications. He accommodated his theory to the facts, not, as is too frequently the case, the facts to the theory. He agreed generally with Willis, in ascribing the origin of disease to certain morbid fermentations, and he conceived the primary changes to take place, not in the solids, but, according to the opinion almost universally adopted at that period, in the fluids; this, indeed, may be regarded as a necessary consequence of the assumed hypothesis.

In one important point he agreed very nearly with Hippocrates, that diseased action consists essentially in an effort of nature to remove some morbid or noxious cause, and that the great object of the practitioner is to assist in bringing about the proper crisis, and to regulate the actions of the system so as to prevent either their excess or their defect. The practice was necessarily of a kind which, in the present day, would be styled somewhat inert, consisting rather in attempts to palliate certain symptoms than in any attempt to counteract or remove their cause. But although we may conceive that the object in view was not always precisely what it would have been, had he not been somewhat biassed by his hypothesis, the mode in which he proceeded to effect his indications is in most cases very judicious. We may, perhaps, venture to affirm that there are few practitioners, even in the present day, who were better acquainted with the juvantia and lædentia, who were more successful in attaining a just medium between excessive caution and undue vigour, and whose proceedings were more guided by the dictates of a sound understanding, enlightened by an extensive range of observation and an ample store of well-digested experience.*

We have spoken of Sydenham in connection with Willis and the chemical physicians, because in many parts of his writings he adopts the hypothesis, that fermentation and other chemical changes in the state of the fluids are the primary causes of disease. Yet we have been, at the same time, especially careful to point out that the distinguishing merit of Sydenham consisted in his not manifesting an undue attachment to any theory, but in devoting himself to the study of disease, and the effect of remedies upon it. This merit was not unperceived by his contemporaries, and we learn that he was held by them in great respect. Yet the general spirit of the age was so entirely devoted to hypothesis and speculation, that he can scarcely be said to have made any great impression upon the general state of medical opinion, or to have materially diverted the mind from an almost exclusive attention to the theories which were then so prevalent. Indeed, with every feeling of admiration for the character and acquirements of Sydenham, it must be admitted that he was not himself fully aware of the great principle, which is the foundation of true philosophy as well in medicine as in every other department of science, that all theory not derived from the generalization of facts is objectionable, and almost necessarily leads to erroneous conclusions. Sydenham's natural sagacity caused him to feel the value of the inductive method, but it was more from this circumstance than from any abstract conception of its importance, that he was induced to adopt it. The state of medical science was indeed scarcely ripe for that reform which had now commenced in many other departments of philosophy. It is more a science of observation than of experiment, and the observations are of peculiarly difficult execution, depending upon the combined operation of various causes, and involving much complication in the effects, the respective proportions of which it is often extremely difficult to ascertain and to appreciate. Hence it required a more matured state of medical knowledge before we could arrive at the great truths which had been promulgated by Bacon, and which were generally recognised in the other departments of science. Although mankind were aware of the importance of observation and experience, they were not sensible of their full value; and it required another century and various successive revolutions of theory before they could be detached from the hypotheses that had been transmitted to them from their predecessors, and had been sanctioned by the authority of so many illustrious names.†

One of these revolutions was produced by the rise of a new theory of medicine, perhaps more captivating than any which had yet appeared, from its scientific aspect and its high pretensions; we allude to the doctrines of the mathematical physicians; or, as they have been termed, the iatro-mathematical School. The rapid advance which had taken place in mathematical science during the latter part of the sixteenth century, and the fortunate application of it to various branches of natural philosophy, induced some of the Italians to apply it to the explanation of the phenomena of the living system. Of these one of the first, both in order of time and of celebrity, was Borelli. He was a profound mathematician, and a man entirely devoted to scientific pursuits, and in his well-known treatise on muscular motion he illustrated, in a very happy manner, the mode in which certain functions of the body may be elucidated and explained on mechanical principles. Some of the data which he assumes are now admitted to be incorrect, and in some cases the deductions are not the fair results of the premises; but upon the whole it is allowed that he established many important points, and considerably advanced our knowledge of the animal economy. The new path of inquiry, which had been thus so successfully opened by Borelli, was soon occupied by many of his contemporaries and pupils, and according to the usual custom on such occasions, it was carried by them far beyond its legitimate limits, and was applied to various topics with which it had little connection. One of the most active and ardent in this pursuit was Bellini, who was a professor at Pisa, and who exhibited such marks of early genius as to become a lecturer at the early age of twenty. His acquirements were varied, and his talents were splendid, but they may be pronounced to be rather showy than solid, and to be more adapted to excite ap-

* *Haller*, Bib. Med. lib. 10, t. iv. p. 188 et seq. *Eloy*, in loco. *Sprengel*, t. v. p. 566-576. *Cabanis*, sect. 12. *Aikin*, in loco. *Renauldin*, in Biog. Univ.

† We have an ample account of the iatro-chemical sect in *Sprengel*, § 13. ch. vi.; its advocates were numerous and respectable, but few were of that distinction which entitles them to be noticed in this sketch.

plause than to advance true science. The mode of reasoning which had been employed by Borelli to explain the action of the muscles, which is essentially a mechanical function, and where such reasoning was therefore appropriate, was extended by Bellini to all the functions and actions of the body both in health and in disease. He maintained not only that every part of the body is under the influence of gravity and mechanical impulse, but that these are the sole agents, and that we may explain all the vital functions merely by the application of the principles of hydrostatics and hydraulics.

The imposing air of the new hypothesis instantly acquired for it a number of converts, embracing many of the most learned men of the age. The body was regarded simply as a machine composed of a certain system of tubes; and calculations were formed of their diameter, of the friction of the fluids in passing along them, of the size of the particles and the pores, the amount of retardation arising from friction and other mechanical causes, while the doctrines of derivation, revulsion, lentor, obstruction, and resolution, with others of an analogous kind, all founded upon mechanical principles, were the almost universal language of both physicians and physiologists towards the close of the seventeenth century. In proportion as the mathematical sect gained ground, that of the chemists declined, while between the two the old Galenists may be considered as nearly extinguished. In Italy and in England the mathematical doctrines had many learned and zealous adherents; it had also some followers in France, although in this country as well as in Holland and Germany, the chemical theory still continued to prevail.*

When we consider the very great influence which the iatro-mathematical sect exercised over the theories of their contemporaries, we may perhaps be surprised that it did not produce any very decided or immediate effect upon their practice. In fact their reasoning was more applicable to physiology than to medicine, for while it appeared to afford a satisfactory explanation of the phenomena of muscular contraction, of the circulation, and of the other functions in which motion was concerned, it was obviously less applicable to the explanation of the obscure and secret agencies by which diseased action is either produced or removed when present. It was, indeed, frequently employed by the pathologist to explain the proximate cause of disease and the operation of remedies, but, except in a few instances, it can scarcely be considered as having had much effect upon the actual treatment. For the most part the practice that was adopted by this sect was founded upon the principles of the humoral pathology, and may be said to have been fundamentally that of the Galenists, although with considerable additions, derived from the more energetic treatment and the enlarged materia medica of the chemists. The great advantage which the science of medicine derived from the mathematicians was of an indirect nature, depending upon the habit of close reasoning and strict deduction, which is requisite in all mathematical inquiries, and which, although in this instance incorrect in the application, and sometimes even founded upon a fallacious basis, were detailed with much labour and ingenuity, and tended both to improve the intellectual powers of the individual, and to raise the character of the medical profession.

During this period, while the minds of men were engaged in these controversies, and while so much attention was paid to theoretical reasoning, the practical part of the science was apt to be regarded as of secondary importance. Certain individuals, indeed, among whom Sydenham may be mentioned as a most illustrious example, contributed in an eminent degree to improve our knowledge of the phenomena of disease and of the effect of remedies upon it; but it must be confessed that for the most part medical men were more anxious to establish their favourite doctrines than to investigate the truth, and we find that, in the account which they give of the details of their practice, they appeared to be much more influenced by the desire of assimilating their experience to the tenets of their sect, than of inquiring how far these tenets were themselves sanctioned by their experience. In some instances there is too much reason to suspect that the operation of the theoretical views of the practitioner was decidedly unfavourable. The opinion which was entertained by the chemical physicians of the nature of fever, that it depended upon an acrid state of the fluids, led to the indiscriminate use of alkalies in all cases which were considered as belonging to this class of diseases. Again, certain hypothetical opinions which were entertained by the mathematical physicians respecting the mechanical condition of the blood, caused them to employ the lancet in cases where we should now consider it as decidedly injurious. But it does not require the illustration of particular cases to prove the position, that where the theoretical views which were entertained of the nature of the disease were incorrect, and where the practitioner was guided by these views, the result must have been frequently unfavourable. Happily, however, for mankind, there were not wanting individuals who rose superior to the spirit of the age, who disregarded the controversies of the contending sects, and who followed the inductive method of studying medicine which had now been introduced into philosophy by the commanding genius of Bacon. Besides Sydenham, our own country may justly boast of the names of Morton, Mead, and Freind,† who, although not without their bias towards particular opinions, were men of superior minds, who were fully aware of the imperfection of medical science, and of the value of experience as the means of remedying this imperfection.

CHAP. X. — *Account of the sect of Vitalists—Van Helmont—Stahl, his system—Hoffman, his system, pathology, influence of his doctrines—Solidism—Baglivi—Disciples of Stahl.*

While the medical world was thus divided be-

* *Sprengel*, sect. 14. *Cabanis*, ch. 2, § 9. In Italy we may select, as among the most eminent of the intra-mathematical sect, Borelli, Bellini, Castelli, and Guglielmini; in France we have the celebrated Sauvages, and in our own country Pitcairne, Charleton, Keill, Jurin, Mead, and Freind; we may remark, however, that some of these, although practitioners of medicine, are principally indebted for their reputation to their physiological writings.

† For the character and writings of these eminent physicians the reader is referred to the respective articles in Eloy and Haller, Bib. Med.

tween the rival opinions of the chemists and the mathematicians, a new sect was gradually rising up, which, although in its commencement it was perhaps equally remote from the principles of true science, became by successive improvements freed from many of its exceptionable parts, and finally triumphed over both the contending parties. It originated with Van Helmont, who commenced his philosophical career as a disciple of the chemical school of Paracelsus. He was a man of a powerful mind, but with a considerable mixture of enthusiasm and even of fanaticism, who became disgusted with the Galenic mode of studying and practising medicine, and embraced the bolder and more efficacious system of the chemists. But he made this great and essential addition to their doctrine,—that the changes which are produced in the body by its own spontaneous actions, as well as by the operation of remedies, are under the influence of a specific agent, which resides in or is attached to the living system, and to which he gave the name of *archeus*.*

It would not be easy to give any exact definition of the term, or to assign the precise meaning which was attached to it. Sometimes he seems to consider it as an abstract principle or power distinct from the material part of the universe; sometimes as a species of element, and at other times as a certain modification of matter which acquires peculiar qualities or agencies.† In consequence of his early training in the chemical school, he occasionally speaks of the archeus as a kind of ferment, and it would appear that he resolves all the operations of the living system and all the functions into certain fermentative processes effected by the action of the archeus. In short the archeus was the convenient and never-failing aid to which he had recourse for the purpose of explaining all the actions of the system either in health or in disease; it was equally the cause of digestion and of sanguification, of fever and of inflammation. Van Helmont, both from the peculiar turn of his mind and from the course of study to which he had devoted himself, was little qualified to watch over the phenomena of disease, or to discriminate between the nice shades which so frequently serve to characterize the different morbid affections. Accordingly it does not appear that he introduced any improvement into the practice of medicine, or indeed into any of the collateral departments; he is solely entitled to be noticed in this place as having laid the foundation for a new series of opinions, which were gradually moulded into one of the most important theories which had occupied the attention either of the physician or the physiologist.‡

Although, strictly speaking, Van Helmont must be regarded as the individual who first stated, in express terms, the great and important principle that the living body possesses powers of a specific nature different from those which belong to inanimate matter, yet so much mysticism and error were mixed with it, that it produced little effect on the opinions of his contemporaries. Nearly half a century had elapsed after his death, during which time the physicians and physiologists were still defending the doctrines of the chemists and the mathematicians each against their respective antagonists, when a new impulse was given to medical theory by the appearance of the celebrated Stahl, who was born at Anspach in the year 1660. His education was almost exclusively occupied with the study of medicine. At the age of twenty-three he became a public lecturer, and from this time he bore a conspicuous rank in his profession, both as a teacher and a practitioner, during the remainder of his life. He was brought up in the principles of the chemical school, and hence his attention was early turned to the study of chemistry, in which science he effected a still greater revolution of opinion than in that of medicine. He possessed a character and disposition well adapted to become the founder of a new sect. He had great activity of mind united to great industry; he was zealous and enthusiastic, at the same time inclined to fanaticism and mystery; he was bold, confident, and arrogant, fully impressed with the importance of his own opinions, and disposed to place little reliance on those of others. His arrogance, however, probably induced him to enter upon investigations which he might not have attempted had he contented himself with following the track of his predecessors, and to his declared contempt for the learning of his contemporaries we may consider ourselves as in part at least indebted for his original speculations, and for the actual additions which he made to our knowledge. This contempt and arrogance were carried to such an extent that he professed to set little or no value upon any of those studies that are usually associated with medicine, even that of anatomy; and he appeared to pay no regard either to the assertions or the arguments of his contemporaries when they opposed any of his favourite doctrines. Besides his ardour in the pursuit of medical science, he appears to have had a decided turn for metaphysical reasoning, and in the formation of his theories he was probably influenced by the doctrines of Descartes, which were then embraced by many of the learned men of Europe.

Stahl saw the errors and deficiencies of both the prevailing theories; he therefore laid it down as a fundamental position, that neither chemical nor mechanical reasoning is applicable to the phenomena of life, and he consequently bestowed all his attention on the study of what he termed vital actions. These actions he refers to the operation of a principle which he styles *anima*, and which in many respects resembles the archeus of Van Helmont. (Physiol. sect. 1, numb. 3, sect. 13, et alibi.) The basis of the Stahlian doctrine is similar to that of the Cartesian system, that matter is necessarily and essentially passive or inert, and that all its active properties or powers are derived from an immaterial animating principle, which is superinduced upon it or added to it. It is by the operation of this spiritual principle upon the ma-

* He probably took the term from Paracelsus, who speaks of it as a new word which he had introduced into medicine; Chirurg. Mag. tract 5, cap. 15.

‡ *Eloy*, in loco. *Haller*, Bib. Med. lib. 8, t. ii. p. 518 et seq. *Enfield*, v. ii. p. 458–60. *Goulin*, in Enc. Méth. Médecine, in loco. *Sprengel*, sect. 13, ch. 3: this author gives us a very minute analysis of the writings and opinions of Van Helmont. Although his absurdities are not concealed, we conceive that the account is somewhat too favourable. *Hutchinson's* Biog. Med. v. i. p. 414–423. *Fournier*, in Biog. Univ. in loco.

terial organs of the body that all the vital functions are produced, and it is on the absence or presence of this principle that the difference between living and dead matter essentially depends. Stahl observed with considerable acuteness the action which the mind exercises over the body, and he proved that these effects could not be referred either to a mere chemical or mechanical agent. This point, clear as it now appears to us, had not been distinctly recognised before his time, or rather, it may be said that the contrary opinion formed the basis of both the prevailing theories. But although he laid down this great truth, and established it by incontrovertible arguments, there is considerable obscurity respecting the nature of this immaterial or superintending agent; and when we enter upon the detail of his description, we become involved in a labyrinth of metaphysical subtlety. We are told that the anima superintends and directs every part of the animal economy from its first formation; that it prevents or repairs injuries, counteracts the effects of morbid causes, or tends to remove them when actually present, yet that we are unconscious of its existence; and that, while it manifests every attribute of reason and design, it is devoid of these qualities, and is in fact a necessary and unintelligent agent. He examined with much attention the nature of the different functions, their relation to the anima, and their dependence upon it; he endeavoured to explain the effect of organization, and the mode in which organization operates in producing these functions. In these investigations he displays considerable acuteness, and he contributed materially to advance our knowledge of the laws of vitality; but still his ideas are, in many respects, confused and indistinct, and he is more disposed to enter into subtile disquisitions respecting the nature of his supposed principle, than to examine the actual phenomena of the animal economy, and from them to deduce his general laws.*

Contrary to what is frequently the case, the hypothesis of Stahl had a considerable influence upon his practice. As all the actions of the system are under the control of the anima, and as the office of this principle is to preserve the system in its perfect state, the duty of the physician is reduced to the mere superintendence of its actions, generally to co-operate with its efforts, or if they should be irregular or injurious, which we are to suppose is seldom the case, to endeavour to restrain or counteract them. These views tended to repress the energy of the practitioner still more than the pathological doctrines of Hippocrates, inasmuch as the anima of Stahl was conceived to exercise a more direct influence over the operations of the economy than the φυσις of Hippocrates, which was simply a general expression of these actions, and which, according to circumstances, might be either beneficial or injurious to the system. As a specimen of the mode in which Stahl applied his theory to practice, we may select his doctrine respecting plethora. He supposed that the body had a general tendency to the plethoric state, because he observed that spontaneous evacuations of various kinds occasionally took place, and these he assumed were produced by the provident care of the anima, in order to remove a plethora which must have previously existed so as to render them necessary. An important office of the superintendent principle is therefore to produce the necessary evacuations in order to prevent or remove this plethora, and hence it becomes the duty of the practitioner to watch over the evacuations, to promote them if too scanty, or to repress them if too abundant. (Pathol. pars ii. sect. 1, mem. 2, § 3 et alibi.)

The theory of Stahl, so far as it tended to fix the attention upon the vital actions of the system, and to overthrow the mechanical hypotheses which had so long and so generally prevailed, may be considered as having performed an essential service to the science of medicine. The appearance of metaphysical acuteness which it presented, independent of its real merits, acquired for it a degree of popularity in an age when the attention had been particularly directed to subjects of this description. It certainly produced a considerable revolution both in medical language and in medical opinions; and although Stahl had but few followers who received his doctrines in their full extent, it was partially embraced by many of the most intelligent and learned men of that period, and it has ultimately had a great and extensive influence on the state of the science. Independently of the defects inherent in the system itself, the spirit of inquiry was now so widely diffused, and the importance of patiently investigating the phenomena of the animal economy was so generally admitted, that the merits of all theories were more strictly canvassed and subjected to more severe examination. From the same combination of causes a variety of rival hypotheses were produced, which tended to prevent the exclusive adoption of any one of them in preference to the rest; and the same state of things was still farther promoted by the great number of medical schools which were established in all the great cities of Europe, each of which was anxious to advance its claim to the public attention.

We have given to Stahl the great merit of having clearly perceived and decisively established the important truth, that the operations of the animal economy cannot be explained by the laws either of chemistry or of mechanics, and that we must therefore have recourse to something of a specific nature, peculiar to the living system itself. Yet, although he succeeded in pointing out the insufficiency of the existing theories, the one which he substituted in their place, the action of the superintending anima, was no less difficult to comprehend, was equally hypothetical, and equally liable to objections. His genius was not of a kind which was adapted to slow and patient investigation, and we accordingly find that he either defends his system upon general grounds, or rests satisfied with merely pointing out the errors and deficiencies of his adversaries. A powerful and sagacious mind was still wanting, which might carefully examine into the nature and operations of the powers that exclusively belong to the living body, and after ascertaining the facts, might generalize them, and thus deduce the correct theory. This was a process of much labour and difficulty,

* *Haller*, Bib. Med. lib. xi. t. iii. p 575 et seq. *Eloy*, in loco. *Cullen*, Preface to his "First Lines," p. 12-18. *Sprengel*, sect. 15, ch. 1, t. v. p. 195-270. *Blumenbach*, § 120. *Thomson's* Cullen, v. 1. p. 164-182. *Renauldin*, Biog. Univ. in loco.

one which could only be accomplished by slow degrees, and which it might be expected would require the co-operation of various individuals.

Of those whom we should be disposed to regard as having mainly contributed to this gradual progression, the first in point of time as well as of celebrity is Hoffmann. He was the contemporary of Stahl, and his colleague in the university of Halle; he may be considered likewise as his rival, for although they both contributed so considerably to advance our knowledge of the animal economy, and, to a certain extent, by pursuing a similar mode of reasoning, yet they were persons of very different habits and dispositions, and attempted to attain the same object by very different means. Hoffmann was a prolix and discursive writer, whose collected works occupy many folio volumes, and the very titles of which, as detailed by Haller, extend to no less than thirty-eight quarto pages. (*Haller*, Bib. Med. t. iii. p. 536-576.) It must therefore be supposed that they contain much that is of little value, and exhibit many marks of the hasty manner in which they were composed. Yet he appears to have been a diligent observer and collector of facts, and therefore, notwithstanding the repulsive aspect of his works, they are highly estimated and frequently referred to. He attended much more to the details of practice than his colleague, and, indeed, the basis of his great work, "Systema Medicinæ Rationalis," is essentially practical, in which his physiological and pathological doctrines are, for the most part, introduced in an incidental manner, as supporting or elucidating his practical observations. Of the nature or details of his practice it will not be necessary to enter into any minute examination. It did not differ very materially from that of his contemporaries, although the circumstance of his being less exclusively attached to any single hypothesis has rendered him more disposed to take a candid and unprejudiced view of the various points which would necessarily fall under his observation. In his leading doctrines he must be classed with the mathematical physicians, but at the same time he adopts many of the opinions of the chemists, and indeed not unfrequently derives his indications from the supposed chemical condition of the fluids. But the great and important addition which Hoffmann made to theory, both medical and physiological, is the distinct manner in which he refers to the operations of the nervous system, and its influence on the phenomena of life. Many of the actions which Stahl ascribes to the action of his hypothetical principle, the anima, Hoffmann explained by referring them to the nervous influence, a physical power no less real than that of gravity or chemical affinity, but of a specific nature and operating by its own laws, the knowledge of which is to be acquired by observation and experiment. (*Thomson's* Cullen, p. 195, 6.)

But whatever merit Hoffmann may have had as a practitioner, his reputation with posterity must principally rest upon his merit as a pathologist. Although, as we have stated above, he considered the fluids to be occasionally the primary seat of disease, yet in most cases he conceives it to originate in an affection of the solids. In order to explain this affection, he assumed that what he terms the moving fibre possesses a certain degree of action or tone, which constitutes its natural state, and is necessary for the performance of its functions. Various circumstances, as well external as internal, were supposed either to increase or diminish this tone; if it were increased beyond its due limit, the state of spasm is the result; if it were unduly diminished, the contrary state of atony was produced. This celebrated theory, which under various modifications entered so largely into the speculations of most of the pathologists of the seventeenth century, cannot be maintained in all its parts as it was detailed by Hoffmann; it must, however, be admitted that it made a considerable approach to a correct view of the subject, and that it may be regarded as the germ from which the more mature doctrines of his successors immediately emanated. It has been supposed that he borrowed it from the constricted and relaxed fibre of the ancients, but even if we admit that this may have furnished him with the first hint, it was so far new-modelled and extended by him as to deserve the merit of originality.*

This hypothesis of the nature of the moving fibre, together with the more extensive influence which the nervous system was imagined to exercise over the various operations of the animal economy, may be considered as forming the basis of both the physiology and the pathology of Hoffmann. Unfortunately for the fame of this writer, in consequence of the multiplicity of his works, and the hasty manner in which they were composed, it is very difficult to obtain a consistent or connected view of his theory; but, upon the whole, we conceive that he is entitled to the merit of having materially advanced our knowledge of the laws of the animal economy, and still more, of having pointed out the track which might be successfully pursued by others for the farther advancement of this knowledge. With respect to the works of Hoffmann it may be further remarked, that as in the course of his experience he gradually enlarged and corrected his pathological doctrines, and continued to publish them from time to time, in detached portions, but without giving them in a condensed or abstracted form, we frequently meet with what appear to be inconsistencies and contradictions, and are obliged to collect his opinions rather from inferences and from indirect remarks, than from any clear and explicit statement of them.†

In giving an account of the pathology of Hoffmann, we have somewhat anticipated an important point of medical theory, to which we must now revert. We have had occasion in various

* Cullen, in the preface to his "First Lines," bears ample testimony to the value and importance of Hoffmann's physiological speculations, and acknowledges the use which he had made of them in the formation of his own hypotheses.

† *Haller*, Bibl. Med. lib. x. sec. 877, t. iv. p. 536 et seq. Nouv. Dict. Hist. in loco. *Eloy*, in loco. *Cullen*, preface to his "First Lines," p. 18-25. *Sprengel*, sect. 15, ch. 2. *Blumenbach*, sect. 419. *Goulin*, in Enc. Meth. Médecine, in loco. *Thomson's* Life of Cullen, v. i. p. 182-200. Biog. Univ. in loco. Of his works the following may be selected as the most original and valuable:—Systema Medicinæ Rationalis; Medicina Consultatoria; Opuscula Med. Phys.; Consult. et Respons. Cent.; Pathologia Generalis; Therapia Generalis; Semeiologia; Philosophia Corporis hum. vivi.

parts of this history to notice, that through all the succession of opinions from the time of Hippocrates to the period at which we are now arrived, with a very few exceptions, the hypotheses were all founded upon the humoral pathology. This opinion was maintained equally by the mathematicians, the chemists, and the metaphysicians. The changes that were produced in the system, whether mechanical or chemical, were equally supposed to take their origin from the fluids, while the metaphysician imagined that it was upon the fluids that his immaterial superintending principle exercised its action. We may regard the publication of Glisson's treatise, "De Ventriculo et Intestinis," which appeared in 1671, as having laid the foundation for the change of opinion which afterwards took place respecting this doctrine. It was in this work that the hypothesis of muscular irritability was originally brought forwards, a specific property, which is supposed to be attached to the living fibre, and from which is deduced its peculiar power of contraction.* But the first writer who systematically opposed the theory of the humoral pathology was Baglivi. He was born near the conclusion of the seventeenth century, and after rising to early eminence in his profession, and acquiring a high reputation for his sagacity in the treatment of disease, and for the assiduity which he displayed in the acquisition of medical knowledge, was prematurely cut off at the age of thirty-four. (*Eloy*, in loco. *Haller*, Bibl. Med. lib. xii. sec. 954, t. iv. p. 197 et seq. *Goulin*, in Encyc. Méth. Médecine, in loco. *Chaussier et Adelon*, in Biog. Univ., in loco.) He proceeded upon the Hippocratean plan of watching attentively and accurately describing the phenomena of disease; but he differed from him as to their primary seat, rejecting the principles of the humoral pathology, and placing the causes of them in the altered condition of the solids. His account of the nature of the solids, and the actions of what he terms the moving fibres, is by no means conformable to our modern notions on the subject, and may be pronounced to be incorrect; but the opinion that the fluids are affected secondarily, in consequence of a previous affection of the solids, was a great and important point of theory, which has been gradually gaining ground since the time that it was first promulgated by Baglivi, and may be regarded, with certain modifications, as the current hypothesis of the present day. The doctrine of solidism had, indeed, no direct or immediate effect upon the practice of medicine, but by drawing the attention more to the state of the muscular and nervous systems than to that of the fluids, it tended to correct many of the erroneous opinions which had previously prevailed respecting the actual condition of the system when labouring under disease, and in this way powerfully contributed to improve our knowledge of the relative state of the different parts of the animal economy, and of the operation of remedies upon it. The gradual subversion of the humoral pathology may also be regarded as a remote cause of the favourable reception with which the doctrines of Hoffmann were received, while the attention which he paid to the action of the nervous system contributed, in its turn, still farther to favour the theory of solidism in opposition to that of the humoral pathology.

The theory of Stahl, notwithstanding its defects and inconsistencies, was calculated to make a considerable impression upon the public mind at the time when it was advanced, and it accordingly met with numerous supporters. It clearly pointed out the inadequacy of all the previous hypotheses, founded merely on mechanical principles, to explain the phenomena of vitality, while it was powerfully recommended by its simplicity; and perhaps even its metaphysical aspect might render it not the less acceptable to his countrymen, who were deeply interested in the speculations of Leibnitz, and the controversy to which they had given rise. It was not, indeed, generally embraced in its full extent; but with certain modifications it remained the favourite doctrine with many of the Germans, until it was gradually superseded by the more correct views of Hoffmann, and still further by the powerful and commanding genius of Haller.

Of the followers of Stahl, who adopted his opinions with the fewest alterations, we may select the names of Juncker and Alberti, who were both of them professors in the university of Halle, of which they contributed for many years to support the reputation which it had acquired under their illustrious predecessors. They were both of them voluminous writers, and they devoted a considerable part of their labours to expounding and illustrating the principles of the Stahlian system. But their works being more theoretical than practical, and being intended rather for the purpose of defending certain opinions than for the acquisition of knowledge, are now sunk into oblivion, or are merely referred to as historical records of an hypothesis which formerly engaged so much attention.

With these remarks on the theory of the vitalists we shall close the review of the state of medical science during the seventeenth century. Up to this period we have adopted the chronological arrangement, and by pursuing this method have been enabled without difficulty to trace the successive stages of the progress of our art. But, as we approach nearer to our own times, the number of subjects which claim our notice are so multiplied, that it will be necessary to continue the historical sketch upon a different plan. Disregarding therefore, to a certain extent, the mere order of time, we shall, in succession, give an account of those individuals who have acquired the greatest degree of celebrity, endeavouring at the same time to class them according to the opinions which they adopted, pointing out their connection with each other, and with the general state of medical science.†

* See especially the fifth chapter of the treatise entitled "De fibris in genere." *Eloy*, in loco.

† It may be necessary to observe that we have already somewhat deviated from the chronological arrangement in considering Hoffman and Stahl as belonging to the seventeenth century, although it was not until near the close of it, in the years 1693 and 1694, that they entered upon their office as professors at Halle. But by admitting of this irregularity, we have made the division to correspond more nearly with the changes which took place in the state of medical science.

CHAPTER XI.—*Introductory remarks—General progress of medical science—Boerhaave, character of his writings, his pathology—Gaubius—Gorter—Haller, his character, pathological doctrines, his disciples, his opponents—Whytt—Semi-animists—Sauvages—Cullen, his pathology and practice, his pupils—Brown, his system—Darwin, his system.*

From the revival of letters to the commencement of the eighteenth century, including a period of between two and three hundred years, the great aim and object had been to apply to medicine the same scientific principles which had been found successful in the advancement of the other departments of philosophy. The most distinguished medical writers of that period had therefore employed themselves rather in collecting opinions and in reasoning upon them, than in examining into the grounds on which these opinions had been formed, or inquiring in what degree they were applicable to the explanation of the phenomena of the animal economy. For the most part, as we have had occasion to remark, they failed in their direct object; at the same time, however, a considerable body of information was gradually acquired, and the views which now began to be unfolded in consequence of the pathological speculations of Hoffmann, and the practical observations of Sydenham and the modern Hippocrateans, led to the establishment of the same spirit of inductive investigation in medicine which had been for some time adopted in the other departments of natural science. We have passed over the age of mere learning, and we now enter upon that of observation and experiment. Scholastic disquisitions were completely disregarded, abstract theory was rapidly falling into disrepute, and hypotheses were no longer considered as deserving of attention unless they professed to be derived from the generalization of facts. The necessary result of this state of things has been to detach the mind from the arbitrary influence of theory, to diminish the authority of great names, and to induce the inquirers after truth to rest more upon their own exertions than upon the authority of others. We have, indeed, still to lament the errors and perversions of the human mind, to witness the attempts of ignorance and arrogance to usurp the place which is due to modest desert and patient research; but such attempts for the most part have obtained only temporary success, and after an ephemeral celebrity have been consigned to their merited contempt. In the mean time, notwithstanding these occasional interruptions, the progress of knowledge has been rapidly and steadily advancing. Experiments, well contrived and patiently conducted, have been performed in every department of physiological and medical science; observations have been made with more minuteness, and recorded with more accuracy; our improved knowledge of chemistry has enabled us to introduce the most important reforms into pharmacy, while the discovery of various new articles of the materia medica has given us additional and powerful means of opposing the progress of disease.

While Stahl and Hoffmann were promulgating their doctrines in the university of Halle, the celebrated Boerhaave was teaching medicine with equal zeal, and we may venture to say with more success, at Leyden.* Boerhaave was originally educated for the profession of theology, but owing to some doctrinal scruples he fortunately relinquished his intention, and devoted himself to the study of medicine in all its branches. There are few examples, either in ancient or in modern times, of any individual who arrived at higher eminence, both in general knowledge and in the departments more immediately connected with his profession. His acquaintance with botany and with chemistry were such as to enable him to teach both these sciences with the greatest success; while his lectures and his writings on medicine, both theoretical and practical, were long considered as standards of excellence. He had a mind and character peculiarly well adapted for his situation and the age in which he lived, when a variety of new facts and new hypotheses were brought into view, and when it required a consummate degree of judgment to weigh the opposing evidence, and decide between the merits of the contending parties. His moral qualities were no less admirable than his intellectual acquirements; and if we add to these his elegance as a writer, his eloquence as a lecturer, and his entire devotedness to his profession, we shall be at no loss to account for the celebrity which he enjoyed during his lifetime, and the reputation which he left behind him.

Boerhaave has been compared to Galen, and it may be asserted that he will not lose by the comparison. If Galen possessed more genius, Boerhaave possessed more judgment; while in their scientific acquirements, and in the extent of their information, it would not be easy to decide between them. They were both eminently skilled in the art of availing themselves of the knowledge of their contemporaries in all the branches of science, of applying it to the elucidation of their particular department, and of modelling and combining into a well-digested system all the scattered materials which they obtained from so great a variety of sources. In the stability of their systems, however, we observe a remarkable difference, for while Galen's doctrines were implicitly adopted for many centuries, the system of Boerhaave, notwithstanding its real merits and the applause which it obtained during the life of its inventor, shortly after his death was assailed from numerous quarters, and was unable to maintain its ground. The age in which Boerhaave lived was not one of authority but of investigation, and the enlightened spirit which pervades his own works tended in no small degree to foster that taste for inquiry which led his contemporaries not to rest satisfied with his theories, however beautiful might be their aspect, and however happily they might appear to explain the phenomena of life, if they were found to be based upon principles which were themselves conjectural and gratuitous.

The great object of Boerhaave in the formation of his system was to collect all that was valuable from preceding writers, and by means of these materials to erect a system which should be truly eclectic. The basis of his doctrines is in a great measure mechanical, derived from the hypothesis

* Boerhaave was elected to the chair of medicine in 1709.

of Bellini and Pitcairne, but he unites with this certain parts of the humoral pathology, and adopts some of the opinions of Hoffmann. To these he added various original observations, by which he has given ample proof of his talents as a sagacious practitioner. His language is remarkably perspicuous, and his reasoning, if we admit his premises, is fair and conclusive. But the grand error of Boerhaave consisted in his depending more upon opinions than upon observations, in his endeavouring to form a system which should be composed of the united speculations of others, rather than to ascertain the correctness of the principles from which these speculations were deduced. His system accordingly met with the fate of all such as are built upon hypothesis; it could not stand the test of experiment and observation, and notwithstanding the efforts of some of Boerhaave's pupils, who were zealously attached to their master, it was generally discarded in no long period after the death of its inventor. But although the system of Boerhaave may have yielded to the more perfect and enlarged theories of his successors, he must be ever regarded as one to whom the science of medicine is deeply indebted. His Institutions and his Aphorisms would alone serve to immortalize his reputation as a correct observer and a sagacious practitioner, and if we compare them with any contemporary performance, which is the fair method of judging of the merits of works of science, we cannot fail to recognise their great superiority.*

In forming his system, Boerhaave was not unmindful of the doctrines of Hoffmann, and particularly of the influence which the brain and nerves exercise over the operations of the animal economy. But although he introduces it on certain occasions, and in some instances allows it to act a prominent part,† yet he was by no means fully aware of the extent of its power. This indeed may be considered as the radical defect of his pathological doctrines; he regards the solids too much in the light of mere mechanical agents, without sufficiently taking into account those properties which specifically distinguish them from inanimate bodies. This deficiency was to a certain extent supplied by his nephew Kauw Boerhaave, (*Thomson's* Cullen, v. i. p. 219,) and by his favourite pupil and successor Gaubius, (Ib. p. 220,) who introduced the agency of the nervous system in many cases where it had been omitted by Boerhaave himself. They were both of them men of considerable talents and acquirements, and the improvements which they made in medical theory were of real value. The writings of Gaubius, especially his Nosology and his Institutions of Pathology, were long held in high estimation, and were employed as text books in the medical schools. (*Haller*, Bibl. Anat. t. ii. p. 166, 7. *Eloy*, in loco. *Aikin's* Gen. Biog. in loco. *Thomson's* Cullen, v. i. p. 220, 1. *Desgenettes*, in Biog. Univ. in loco.) In the same connection we may mention the name of Gorter, an eminent professor and practitioner at Harderwyc, who, while, like Boerhaave, he adopted the essential parts of the mechanical theories of his predecessors, made considerable use of the agency of what he termed the vital force in explaining many of the operations of the animal economy. (*Eloy*, in loco *Haller*, Bibl. Anat. t. ii. p. 169, 70. *Sprengel*, t. v. p. 314–16. *Thomson's* Cullen, v. i. p. 218. *Renauldin*, in Biog. Univ. in loco.) The writings of Gorter are very numerous, and prove him to have been an industrious cultivator of medical science, while his great practical work, entitled "Compendium Medicinæ," indicates a talent for correct observation, and an accurate discrimination of morbid symptoms.

But the great support and ornament of the Boerhaavian school was Van Swieten. He was born at Leyden in the last year of the seventeenth century, and was one of the most favoured and meritorious of the pupils of Boerhaave. In consequence of his theological opinions not coinciding with those of the state religion, he was expelled from the university of his native city, in which he held a professorship, and accepted an invitation from Maria Theresa to the court of Vienna. Here honours and distinctions of all kinds were heaped upon him; but these he amply repaid by the unremitting attention with which he devoted himself to the medical school of that metropolis. Of the high reputation which it has since enjoyed he may be said to have laid the foundation, while by the publication of his Commentaries on the Aphorisms of Boerhaave, he demonstrated at the same time the high respect which he retained for his preceptor, and the extent of his own information on all subjects connected with medical science. The Commentaries of Van Swieten contain a large and valuable collection of practical observations, partly the result of the author's own experience, and partly derived from his extensive knowledge of books. He adopted the theory of Boerhaave with little alteration, and in this respect the work must be regarded as fundamentally defective; but the great body of facts which it contains, detailed as they are in a clear and perspicuous style, will always insure it a place in the library of the medical student. (*Eloy*, in loco. *Nauche*, in Biog. Univ. in loco.)

The intimate connection which subsists between the doctrines of pathology and an acquaintance with the laws of the animal economy in its healthy and perfect state, makes it necessary for us to give some account of an individual who, although not a practitioner of medicine, contributed perhaps more to our knowledge of the nature of disease than any one who has hitherto passed under our review. We refer to the great name of Haller, who has been not unaptly termed the father of modern physiology. He was the pupil of Boerhaave, and imbibed from him his thirst for knowledge, his correct judgment, his undeviating candour, his unblemished integrity, and in short all the intellectual and moral qualities which we have admired in the professor of Leyden. But to these qualities Haller added a more extensive and original genius, which led him never to rest upon the unexamined opinions of others, and a clearness of conception which taught him, both in

* *Haller*. Bib. Med. lib. xii. t. iv. p. 142 et seq. *Eloy*, in loco. *Cullen*, Preface to his "First Lines," p. 25–35. *Hutchinson's* Biog. Med. v. i. p. 82 et seq. Nouv. Dict. Hist. in loco. *Thomson's* Life of Cullen, v. i. p. 200–17. *Blumenbach*, Introd. § 418. *Goulin*, in Encyc. Meth. Médecine, in loco. Biographie Universelle in loco.

† See particularly his work entitled "Prælectiones de Morbis Nervorum."

his language and his mode of reasoning, to avoid all ambiguous and undefined terms, and all irrelevant arguments. He possessed a mind at the same time comprehensive and correct, equally adapted for discovering new paths to knowledge, and for investigating those which had been previously entered upon by others. The innate powers of the components of the body, which had been imperfectly seen by Glisson and by Hoffmann, were examined by Haller with his characteristic acuteness, and the result of his long and well-directed experimental research was rewarded by the establishment of his theory of irritability and sensibility as specific properties attached to the two great systems of the animal frame, the muscular and the nervous, to which, either separately or conjointly, may be referred all the phenomena of the living body. But perhaps a still more important service which Haller rendered to science was the example which he held out of carefully abstaining from all opinions founded merely upon speculative grounds, and of deducing his general principles exclusively from experiment and observation. He gave an impulse to science no less by the actual discoveries which he made, than by the spirit with which he conducted his researches, so that we may regard the publication of his Elements of Physiology, as having introduced a new era into medical science.*

It would be incompatible both with the immediate subject of this essay, and with the limits to which it is necessarily restricted, to give a detailed account of the controversies and discussions to which the theory of Haller gave rise. Notwithstanding its merits, and the evidence by which it was supported, it was opposed, either in its full extent or in certain of its parts, by many individuals of high respectability; while on the contrary various experiments were instituted, by which his conclusions were confirmed and his principles extended. Among those who were the most successful in these researches we may select the names of Zimmermann, (De Irritabilitate,) Caldani, (Instit. Physiol.) Fontana, (in *Haller*, sur la Nature Sens. et Irrit. t. iii.) Tissot, (Ibid. t. i. et iii.) Zinn, (Exper. circa Corp. Cal. etc.) and Verschuir. The last of these physiologists particularly distinguished himself by his experiments on the contractility of the arteries, (De Arter. et Ven. Vi. Irrit.) a point which had been left undecided by Haller, but which formed a most important addition to the theory of the action of the vessels, and which had previously been rather assumed as what was probable than deduced from any ascertained facts.

Among the most powerful opponents of the doctrine of Haller we may select the names of Whytt and Porterfield. They were natives of Scotland, and during the earlier part of the last century were residents in the metropolis of that kingdom, and bore a conspicuous part in the scientific institutions for which it was so justly celebrated. The former of them was professor of medicine in the university of Edinburgh at the time when it was rapidly advancing to that high reputation which it afterwards more fully attained under the genius of his illustrious successor Cullen. They opposed that part of the theory of Haller which ascribes all the actions of the living system to certain powers necessarily connected with the material parts of the frame, as well as to the separation of these actions into the two distinct powers of irritability and sensibility.† The controversy which Whytt carried on with Haller was conducted with acuteness and ability, but it manifests a degree of acrimony which it is impossible not to regret, particularly as occurring in an individual who was otherwise so much entitled to our respect. And this is more especially the case when we consider the nature of the objections which he urged against the Hallerian hypothesis, which were rather of a metaphysical nature than such as were either founded upon experiment or deduced from observation. His doctrine of the vital motions of the body, which formed the principal subject of the controversy, may be regarded as intermediate between that of Haller and Stahl, or rather compounded of the two. He attributes these vital motions to the operation of the sentient principle, which is supposed to be something distinct from the corporeal frame, at the same time that it is necessarily attached to it, and is under the influence of physical causes, not like the anima of Stahl, acting by a species of independent consciousness and volition. The great error which pervades the speculations of Whytt and Porterfield consists in their reasoning more upon metaphysical than upon physical principles, and in their assuming certain powers, the proof of which rests more upon their supposed necessity to account for the actions of the system than upon any independent evidence that we have of their existence. They did not indeed, like the Stahlians, consider the sentient principle as something independent of the body, and only as it were appended to it, but as a principle or power necessarily belonging to the living body, and imparting to it its vitality, although essentially distinct in its nature from any of the properties of a mere material agent. Whytt may be regarded as the founder of the sect which obtained the name of the semi-animists, which, under various modifications, included some of the most distinguished physiologists both in this country and in France. Of the latter, one of the most eminent was Sauvages; he was a native of Languedoc, and received his education at Montpellier, which, during the early part of the eighteenth century, held a very high character as a school of medicine. In 1734 he was appointed one of the professors in the university of that city, and during the remainder of his life contributed materially to maintain its credit by his talents both as a writer and a teacher. His reputation with posterity will principally rest upon his methodical nosology, a work which contains an arrangement of diseases into classes, orders, genera, and species, on the same plan which had been employed in the arrangement of the subjects of natural history. The Nosology of Sauvages is a work of great and original merit, which,

although now in some degree superseded by the improvements of later writers, mainly contributed to the advancement of medical knowledge by producing accuracy in the use of terms and in the discrimination of the characters of disease. (*Eloy*, in loco. *Haller*, Bibl. Anat. "Boissier," t. ii. p. 300–4, § 999.)

The same kind of service which Haller rendered to the science of physiology was performed for that of the practice of medicine by his contemporary Cullen. Among those who have made the study of medicine their professed pursuit, no one, since the revival of letters, has risen to greater eminence during his life-time, nor has left behind him a higher reputation than this celebrated individual. During the greatest part of a long life, he was engaged in the teaching of medicine or some of the collateral sciences, first in the university of Glasgow, and afterwards in that of Edinburgh, which latter he contributed, in no small degree, to raise to the rank, which it long held, of the first medical school in Europe. His peculiar excellence as a lecturer afforded him an ample opportunity of promulgating and enforcing his doctrines, while their real merit, no less than the mode in which they were announced, rendered them in the highest degree popular among his pupils and contemporaries. He possessed an acute and ardent mind; he was well skilled in the medical literature both of the ancients and the moderns, but he had no undue respect for the opinions of others on the mere ground of authority. He detected the defects of former hypotheses with shrewdness and sagacity, while he proposed his own views with a degree of candour and modesty which tended to render them the more acceptable, and disposed his audience to receive them in the same spirit with which they were proposed.

With respect to his physiological writings, they afford, in some respects, a remarkable contrast to those of Haller; for while the latter are extended to a great length, and are filled with the most minute and elaborate details, the former are no less remarkable for their compressed brevity, consisting principally in general views and abstracted deductions. Contrary, however, to what is so frequently the case with respect to works of this description, they are not to be regarded as mere speculative positions, but as the condensed result of patient research and extensive observation. Some of the leading doctrines of his pathology were professedly borrowed from Hoffmann; but to these he made many important additions by taking advantage of the various improvements that had been made in physiological knowledge, principally by means of Haller and his pupils. Still later discoveries in this science, and in that of chemistry, have indeed proved that certain parts of his system are not tenable, and that others require to be considerably altered and modified; but it may be asserted that no one produced a more powerful and lasting effect upon the state of medicine in all its branches, both theoretical and practical, than Cullen. But his great and appropriate merit, and which entitles him to the admiration and gratitude of posterity, is the sagacity and diligence which he manifested in the description and discrimination of the phenomena of disease. In this talent he may be considered as rivalling Sydenham or any of his most distinguished predecessors, while the recent improvements in physiology and the other branches of medical science gave him an advantage which he did not fail duly to improve. In his treatment of disease he manifested no less judgment and sagacity than in the formation of his theories. He was prompt and decisive, without rashness; he estimated the powers of remedies by a cautious and accurate examination of their effects, with little bias from hypothesis, and with even somewhat of a sceptical disposition of mind, which prevented him from falling into those errors and inconsistencies to which the practice of medicine is so peculiarly obnoxious.

In giving an account of the system of Boerhaave we remarked that in its formation he proceeded upon the eclectic plan, founding it upon the opinions of others, which he endeavoured to connect together and to mould into a consistent and uniform theory. Cullen adopted the more philosophical mode of generalization and induction. He disclaims all hypotheses and theories not immediately derived from facts, and made it his great business to collect, by actual observation, the materials from which he might deduce his general principles. In this object he was eminently successful, and it is this which gives his writings their great value, a value which they must ever retain amidst all the revolutions of opinion, which attach to medicine more than to any other branch of science. But, although he was so sensible of the advantage of the inductive mode of investigation, he was not a mere empirical practitioner, who disregarded all theoretical reasoning, and never ventured to go beyond the simple result of experience. On the contrary, he inquires in all cases into the remote and primary causes of disease, and endeavours to deduce from them his indications of cure. Many of his individual speculations are indeed remarkable for their subtilty and refinement, and may be characterized as exhibiting more ingenuity than judgment. At the same time it is not a little remarkable that these speculations, however carefully they were elaborated, had but little influence on his practice; and it is gratifying to observe with what caution he applies his hypotheses to explain or direct his method of treating disease.

His great work, entitled "First Lines of the Practice of Physic," is the one on which his reputation will principally rest; but the merits of his Institutions, of his Nosology, and of his Lectures on the Materia Medica, are each of them sufficient to have entitled him to a distinguished rank among the improvers of medical science. The last of these works, in which he takes a more philosophical view of the operation of remedies than had been done by any of his predecessors, is one of peculiar value. It contains a great variety of important pathological observations, together with a complete theory of therapeutics, and being the latest of his publications, we find in it his more matured and corrected views on many topics which had been treated in his former works. In none of them do we find more of that spirit of rational scepticism to which we have alluded above, and which led him to be more confident in opposing the opinions of others than in maintain-

ing his own. Like Haller, with whom we have already taken occasion both to compare and to contrast him, he contributed to introduce into medical reasoning a philosophical spirit, which has produced a permanent and highly salutary effect upon the healing art, and which associates the name of Cullen with those of the great benefactors of the human race.

It is not easy to give, in a short compass, an account of the pathological doctrines of Cullen, because they consisted rather of a number of individual parts, as applied to the explanation of particular phenomena, than of one comprehensive system, which constituted a general theory of diseased action. The foundation of the system is, however, sufficiently simple; that the living body consists of a number of organs, which are all of them possessed of powers of a specific and appropriate nature, distinct from those which are attached to inanimate matter. These powers are so ordered, that they have a tendency to preserve the whole machine in a perfect state, when its actions and functions proceed in their ordinary course. When any irregularity supervenes, either from internal or external causes, if it be not in an excessive degree, the self-regulating principle is sufficient to control the operation of the morbid cause, and to restore the system to its healthy condition. This regulating principle, or, as it was termed, the *vis medicatrix naturæ*, differs essentially from the archeus of Van Helmont or the anima of Stahl, inasmuch as it is supposed not to be any thing superadded to the body, but one of the powers or properties necessary to its constitution as a living system, and the existence of which is recognised by its effects. Although the laws of gravity and of chemical affinity affect the animal body, so far as it is composed of material organs, yet its appropriate actions are under the immediate influence of the specific laws of vitality. Hence all explanations, depending upon mere mechanical or chemical reasoning, were abandoned, and in their place was substituted the vital action of the parts, and more especially that of the extreme branches of the arterial system, or, as they are styled, the capillary arteries. Although it may appear that both Stahl and Hoffmann had to a certain extent preoccupied the ground which was taken by Cullen, as to the foundation of his system, and although the system, as detailed by him, is defective in some of its subordinate parts, yet we must admit that the ample and explicit manner in which it was stated gave it the aspect and much of the merit of novelty, while the applications which he made of it were frequently just, and always ingenious. His physiology and his chemistry were not in all cases correct; he did not pay sufficient attention to the distinction between the powers of the muscles and the nerves, which had been so well discriminated by Haller, and he even confounds their physical structure. But with all these abatements we still regard the pathology of Cullen with much respect, and consider him as one of those who greatly contributed to improve the science no less than the practice of his art.*

What may be termed the Cullenean school of medicine, including both his numerous pupils and the writers who either embraced his peculiar opinions, or adopted his method of investigation, comprehends a large proportion of the most distinguished of the British physicians during the remainder of the eighteenth century. The rational empiricism, as it has been styled, which he so firmly established, both by precept and example, has, in this country at least, so far superseded the taste for mere speculation and hypothesis, that we are perhaps disposed to run into the opposite extreme, and to undervalue all attempts to investigate the abstract principles of pathology, and to employ ourselves solely in the accumulation of facts, without duly attending to the general conclusions that may be deduced from them.†

We have, however, to notice one singular exception to this remark, where an hypothesis was advanced, of the most bold and lofty pretensions, disdaining the support of facts and experience, and professing to explain all the phenomena of life and of disease by a few simple aphorisms. In tracing the history of science, although it is proper for the most part to estimate books and opinions solely by their intrinsic merit, without any regard to the personal character of the author, yet we find them on some occasions so intimately connected that it is impossible altogether to separate them. This is the case with the celebrated Brown, whose theory appears to have originated as much from spleen and disappointment, and a determination to oppose the doctrines of Cullen, as from a more legitimate motive.

Neither the education of Brown nor his natural character were of the kind the best adapted for the prosecution of medical science. He was originally destined for the ecclesiastical profession; and when he afterwards entered upon that of medicine, he never devoted himself to those elementary studies which are indispensably necessary to a correct knowledge either of theory or of practice. But what he wanted in knowledge he endeavoured to supply by the force of his own genius, and by meditating upon a few general or abstract principles, he ventured to form a new system of pathology, which he announced with a

* For a minute detail of the opinions of Cullen and those of his immediate predecessors and contemporaries, the reader is referred to the learned and ample work of Dr. Thomson, which may be characterized as containing a philosophical history of medicine and pathology during the beginning and middle of the eighteenth century. The account which is given of Cullen's pupils must be perused with much interest, an interest which, in the case of the writer of this article, is exalted by the sacred sentiment of filial piety; p. 461, 644-6. See also *Sprengel*, t. v. p. 359-366. We think that this writer, in criticising the doctrines of Cullen, is somewhat deficient in that candour for which he is in most cases so conspicuous; Encyc. Brit. in loco; *Aikin's* Gen. Biog. in loco; *Kerr*, in Brewster's Encyc. art. "Cullen.

† In this brief sketch we can do no more than merely mention the names of some of our countrymen, who, either by the publication of single cases or of monographs on certain diseases, have contributed to the advancement of pathological or practical knowledge. Among others we may select those of Gregory, the able successor of Cullen, Pringle, M'Bride, Huxham, Fothergill, Cleghorn, Brocklesby, Lind, and Russel. In our own times we have had the no less illustrious names of the Hunters, of Percival, Withering, Johnstone, Falconer, Heberden, Baillie, Haygarth, Ferriar, Currie, Willan, Bateman, Marcet, and Parry. In mentioning the name of Gregory, the writer must be allowed to express the feelings of respect and regard which he has always felt for his preceptor. The elegance of his literary taste, his clear and comprehensive judgment, and more especially the interesting mode in which he conveyed his instruction, all contributed to make him one of the most distinguished ornaments of his profession.

degree of confidence that, while it exhibited the strong powers of his understanding, proved no less the deficiency of his information. Medicine, which had hitherto been a conjectural art, was now to be built upon a few certain and fixed principles, which, by superseding all that had been previously written upon the subject, and by being independent both of observation and of experience, required for its attainment little previous study or learning. The novelty of the attempt, the easy access which it promised to a science which before appeared of difficult approach, and the plausibility of some of its leading positions, acquired for the new theory a prodigious degree of popularity in the university of Edinburgh, where it was first promulgated. Brown had been, in the first instance, patronized by Cullen; but from some causes, both of a personal and a professional nature, which it is not difficult to comprehend, he forfeited the good opinion, and became the bitter antagonist of the doctrines of his former friend. The controversy to which this schism gave rise was carried on for some years with great vehemence, and was by no means confined to the place where it originated. In this country the Brunonian system obtained many adherents when it was first proposed, principally indeed among the students or younger members of the profession; while in some parts of the continent, more especially in Italy, it was adopted by men of learning and science, and became the prevailing hypothesis in some of the most respectable medical schools.

The general principles of the theory are few and simple. He assumed that the living body possesses a specific property or power, termed excitability; that every thing which in any way affects the living body acts upon this power as an excitant or stimulant; that the effect of this operation, or excitement, when in its ordinary state, is to produce the natural and healthy condition of the functions; when excessive, it causes exhaustion, termed direct debility; when defective, it produces an accumulation of excitement, or what is termed indirect debility. All morbid action is conceived to depend upon one or other of these states of direct or indirect debility, and diseases are accordingly arranged in two great corresponding classes of sthenic or asthenic; while the treatment is solely directed to the general means for increasing or diminishing the excitement, without any regard to specific symptoms, or any consideration, but that of degree, or any measure but that of quantity. Such general views and sweeping doctrines, however alluring to the uninformed or the mere theorist, are altogether inapplicable to practice; and it is a subject for our admiration how they could be for a moment entertained by any one who had studied the phenomena of disease, or who was acquainted with the intricate and complicated relations of the different functions and actions of the living system. Accordingly in this country, where, in consequence of the prevalence of the Cullenean school, the attention was more directed to practical than to theoretical details, the professed adherents of Brown were neither numerous nor influential; and even in Italy, where for some time it enjoyed considerable popularity, it has long ceased to be maintained. Yet it must always occupy a distinguished place in the history of medical science, as exhibiting a remarkable example of the force of original and unaided genius in erecting a system plausible and captivating in its aspect, but devoid of the essential support of facts and observations, and therefore fated to share the lot of all systems built on so untenable a basis.*

In connection with Brown, we must notice a theorist whose general principles bore a considerable resemblance to those of the "Elementa Medicinæ," but whose character, talents, and acquirements were of a totally opposite kind. The "Zoonomia" of Darwin exhibits genius and originality; but in no other respect does it bear any resemblance to its prototype. Darwin possessed a knowledge of medicine and all the collateral sciences in their full extent; he was familiar with practice, and had a taste for minute detail and experimental research which, while it appeared to qualify him for a medical theorist, enabled him to give to his system an imposing aspect of induction and generalization. His speculations, although highly refined, profess to be founded upon facts; and his arrangement and classification, although complicated, seems consistent in all its parts. No theory which had ever been offered to the public was more highly elaborated, and appeared to be more firmly supported by experience and observation, while every adventitious aid was given to it from the cultivated taste and extensive information of the writer. Yet the Zoonomia made little impression on public opinion; its leading doctrines rested rather upon metaphysical than upon physical considerations, its fundamental positions were found to be gratuitous, and many of the illustrations, although ingenious, were conceived to be inapplicable and inconclusive. It is now seldom referred to, except as a splendid monument of fruitless labour and misapplied learning.*

CHAPTER XII. — *Remarks on the state of practical medicine at the conclusion of the eighteenth century — State of medicine in France, Lieutaud—State of medicine in Germany, De Haen—State of medicine in Italy, Morgagni, Burserius, Rasori—Epidemics—Improvements in pharmacy.*

While the British physicians were principally occupied in collecting facts and recording their observations, and, with the exception of the temporary suspension which was occasioned by the Brunonian controversy, were more intent in adding to the stock of knowledge than in forming systems, the continental physicians were more disposed to pursue the eclectic plan of Boerhaave. In France this was accomplished with the most success by Licutaud. He was a native of Provence, and was for some years a professor at Aix; in 1749 he was appointed physician to the royal

* *Beddoes's* Observations, prefixed to his edition of Brown's Elements; a writer possessed of originality and genius, but perhaps not unaptly characterized by Rothe as "a blind adherent of the new chemists and of Brown." *M'Kenzie*, in Brewster's Enc., art "Brown." *Parr's* Dict., art. "Brunonian System." *Aikin's* Gen. Biog., in loco. *Sprengel*, t. vi. p. 155-158, 315-334. *Suard*, in Biographie Universelle, in loco.

hospital at Versailles, and finally to the court of France. He was eminent both as a practitioner and an anatomist; his great work, the "Synopsis universæ Praxeos Medicæ," published in 1765, contains much information on all topics connected with medicine, and is valuable from its real merits in this respect, while it is interesting as affording a correct view of the state of medical science in France at that period. With respect to his general principles, he was an eclectic, uniting certain parts of the old doctrines of the mathematicians and the humoralists with those of Hoffman and the vitalists. (*Hutchinson's* Biog. Med. vol. ii. p. 63 et seq.) Upon the whole, however, we conceive that we shall not be accused of partiality or want of candour if we give it as our opinion, that the views of Lieutaud and his countrymen are less matured than those of his contemporaries in this island or in Holland. We may remark, in speaking of France, that for many years the great seat of medical science in that country was Montpellier. Its university was established in the thirteenth century, and was one of the earliest of those which rose to any considerable eminence; a distinction which it maintained until it was rivalled by that of Paris, which gradually acquired its splendid reputation during the course of the seventeenth century. To the name of Sauvages, who was mentioned above as distinguished for his learned work on nosology, we may add those of Bordeu, Barthez, and Astruc as among the most eminent members of the school of Montpellier. (*Moreau de la Sarthe*, Encyc. Méth. Médecine, in loco.)

Of the medical schools of Germany, the most celebrated during the seventeenth and eighteenth centuries was Vienna. We have already mentioned the exertions that were so successfully made for its advancement by Van Swieten, who was appointed one of its professors in the year 1734. After he had occupied this situation for about twenty years, he associated with himself his countryman De Haën, who materially contributed to support the reputation of the university, particularly by his talents as a practitioner. His great work, entitled "Ratio Medendi," is a valuable repository of facts and observations; upon which we may make the same remark that we offered above respecting Lieutaud's "Synopsis." De Haën has been characterized as a man of great learning united with much practical skill, and a talent for correct observation; but, on the other hand, he appears to have been unreasonably prejudiced against new opinions, and even improvements, in his art; for not only was he one of the most zealous opponents of Haller's theory, but he was no less decided in his opposition to the practice of inoculation, and to the use of various new remedies, which were at that period introduced into medicine, the value of which is now generally recognised. The state of medical theory then prevailing in Vienna was nearly the same with that which was taught in the universities of Leyden and Paris; the doctrines of the humoral pathology may be considered as forming the basis of their hypotheses, but upon these was engrafted a certain portion of the new views respecting the actions of the nervous system and the contractibility of the muscular fibre.

In Italy, which so early acquired a high degree of celebrity for its medical schools, and which still retains a considerable portion of its former reputation, the sciences of anatomy and physiology were cultivated with success, while they were but little attended to in the other parts of Europe. What may be styled anatomical pathology took its rise in Italy in the seventeenth century. The individual to whom the merit of having opened this new road to the improvement of medical knowledge is principally due is Bonet, (*Haller*, Bibl. Med. lib. 10, § 750. t, iii. p. 236 et seq. *Eloy*, in loco. *Dezeimeris*, Arch. Gén. de Méd. xx. 158, 9,) who was born at Geneva in 1620, and at an advaneed period of his life published his great work entitled, "Sepulchretum," which was afterwards enlarged by his learned and industrious countryman Manget. (*Haller*, Bibl. Anat. lib. 7, § 749, t. i. p. 103 et seq. *Haller*, Bibl. Med. lib. 11, § 889, t. iii. p. 603 et seq. *Eloy*, in loco.) The Sepulchretum has been styled "the Library of true Pathology;" it consists of a great collection of cases, in which we have a history of the diseases with the appearances found upon dissection. The plan which had been commenced by Bonet and Manget was followed up by Valsalva, an eminent professor of Bologna, and was still farther perfected by the illustrious Morgagni. This eminent anatomist was a pupil of Valsalva's, and afterwards became professor in the University of Padua, where for nearly sixty years, until his death, which took place in 1771, he devoted himself without intermission to the study of his favourite pursuit. The principal works of Morgagni are his "Adversaria Anatomica," his "Epistolæ Anatomicæ," and more especially his great pathological collection entitled "De Sedibus et Causis Morborum per Anatomiam indagatis." It proceeds upon the plan of Bonet's Sepulchretum, and contains the observations which were made both by himself and by Valsalva, and has always been regarded as a repository of facts and observations on anatomy and pathology uncqualled in extent and in accuracy. (*Eloy*, in loco. *Haller*, Bibl. Anat. lib. 8, § 797, t. ii. p. 34 et seq. *Haller*, Bibl. Med. lib. 12, § 1029, t. iv. p. 424 et seq. *Renauldin*, Biog. Univ. in loco.)

The Institutions of Berserius afford a favourable view of the state of medical science in Italy at this period. He was born at Trent in 1724, studied first at Padua and afterwards at Bologna; he was for some years a professor in the university of Pavia, and finally removed to Milan, where he died in 1785. (Vide Præf. ad Instit. Med. Prac. ed. Lips. 1787.) Burserius was rather an eclectic than an original theorist, but his work is much valued for the information which it contains, and much admired for the elegant manner in which the information is conveyed. Like his contemporaries in Holland, France, and Germany, his doctrines are essentially founded upon those of the humoralists, but to these he unites various parts of those of the solidists and vitalists, and has proved himself deserving of the praise, not only of learning, but of candour and judgment.

We have already had occasion to remark upon the effect which was produced in Italy by the theory of Brown; it was embraced by many of the learned men of that country, and for some

time acquired a considerably greater ascendency over public opinion than it possessed even in its native city. It was not only defended in their publications, but its doctrines were applied to practice, and it was not until their insufficiency had been detected by fatal experience that the delusion was removed.* At the conclusion of the eighteenth century it would seem that the medical theories of the Italians were considerably similar to those of the Cullenean school, and that the Italians, like the English physicians, were little disposed to form systems of medicine, but devoted themselves principally to the cultivation of anatomy and physiology, in addition to the more immediate studies of their profession.

In tracing the additions and improvements which the science of medicine received during the eighteenth century, we must not omit to notice the descriptions of new diseases, either those which were conceived to have actually originated during this period, if there were any such, or those which had not been previously discriminated with sufficient accuracy from others that in many respects resembled them. The various epidemics which, from some unascertained and unexplained causes, have at different times passed over large portions of the surface of the earth; the endemic diseases attached to particular situations, originating in some circumstance connected with the atmosphere, soil, or climate of certain districts, or in the occupation or mode of life of its inhabitants; and lastly, the contagious or infectious diseases, which have invaded entire cities or communities from unknown or at least obscure causes, and after spreading destruction on all sides, have disappeared from causes equally unascertained.

The first of these classes, the epidemic diseases, were made an especial object of attention, in the latter part of the seventeenth century, by Sydenham, whose remarks on them are among the most interesting of his works; also by Morton and by Ramazzini: at a somewhat later period we have the valuable observations of Huxham, of Lancisi and Torti in Italy, and of Stoll at Vienna. The science has been much enriched by various descriptions of the diseases incident to the army and navy, among which we may particularly notice those of Pringle, Brocklesby, D. Monro, Hunter, Lind, Hillary, Blane, Trotter, Larrey, and Desgenettes.† The formidable disease which has been emphatically termed the plague, as it appeared in London, the Low Countries, Marseilles, Moscow, and other parts of Europe, in the latter part of the seventeenth and the beginning of the eighteenth century, and as it still exists in Turkey, Egypt, and the adjoining countries,‡ as well as the less formidable, although more extensive visitations of the influenza, have each had their historians; and it is truly gratifying to observe that in most cases the writers have been more anxious to collect facts and to obtain correct information than to support any particular theoretical views.§

In reviewing the state of medical science during the eighteenth century, and tracing its gradual advancement, we are naturally led to remark upon the great additions which have been made to pharmacy, both in regard to the introduction of new articles into the materia medica, and the improvement that has taken place in the preparation of various substances, and the mode of their administration. It has been remarked that in proportion as our knowledge of the virtues and qualities of medicines has been matured, our pharmacopœia has been simplified, both as to the number of articles employed and the mode of compounding them. Accordingly, if we compare the successive editions of the British pharmacopœias and dispensatories, we shall find that a number of superfluous and inert substances have been from time to time rejected, and that the complex formulæ of the older physicians have been reduced in the same proportion. At the same time some substances of real efficiency have been added, while the improvement in chemical science has enabled us to obtain the active principles of these substances in much more condensed and commodious forms. This remark may be illustrated by Peruvian bark, a remedy which for a long period afforded a fertile field for controversy both as to its power over disease, the nature of its operation, and the mode of its administration. Practitioners have long been aware of the futility of most of the points which were the subject of so much warm and even acrimonious discussion, and are satisfied with recognising its value as a powerful curative agent in certain diseases, without endeavouring to discover the nature of the occult qualities on which its operation depends; while the chemist has lent his aid in pointing out a mode by which its active proximate principle may be procured, detached from the inert matter with which it is naturally combined. The skill of the modern chemist has likewise been most beneficially exercised on the metallic preparations; giving them more fixed and definite combinations, pointing out the modes by which they may be produced with more ease and certainty, and ascertaining the chemical relation which they bear to other substances, so as to indicate how they may be combined with them without decomposition, or even with an increase of their activity.

* Rasori of Genoa appears to have been the first who made his countrymen acquainted with the doctrines of Brown, of which he was a zealous adherent; subsequently, however, he found reason, from the result of experience, to change his opinions, and very candidly and honestly expressed his conviction of their erroneous tendency. An ample account of the pathological doctrines which are at present the most generally received in Italy, under the title of "Nouva Dottrina Italiana," may be found in the various publications of Tommasini, the learned professor of Bologna.

† For a very complete list of works on these subjects the reader is referred to the valuable work of *Professor Ballingall* on Military Surgery, p. 227 et seq.

‡ Hecker's account of the "Black Death," which ravaged so large a portion of the globe in the fourteenth century, may be mentioned as a work worthy of our notice, both as containing many interesting details of this tremendous pestilence, and as exhibiting a curious specimen of medical hypothesis.

§ For the names of the authors who have treated on these topics, we refer to the respective articles of this work. Copious lists of authors may also be found in *Young's* Medical Literature, a work no less remarkable for its learning than for the condensed form in which it is communicated. Much valuable information on this subject will be found in *Sprengel*, sect. 16. ch. 3, art. 2

CHAPTER XIII. — *Cursory remarks on the state of practical medicine since the commencement of the present century—Difficulty of acquiring medical experience—State of medicine in Great Britain—Pathologists of France—Physiologists of Germany—Medical journals—Medical societies—Schools of medicine—Suggestions for the improvement of medical science.*

As the historian of medicine approaches nearer to his own times, he finds his path encumbered with almost insurmountable difficulties. The subject on which he has to treat differs, perhaps, from every other branch of science in this circumstance, that our actual information does not increase, in any degree, in proportion to our experience. Hence it follows that the accumulation of materials frequently rather retards than promotes its progress. In other sciences, although truth is not to be attained without a certain degree of laborious research, yet to those who are willing to bestow on it the requisite attention, it is for the most part attainable, or, if it still elude our grasp, we are at least sensible of the deficiency, and can generally ascertain the precise nature of the obstacles which impede our progress. In other sciences, when we enter upon an inquiry, or propose to ourselves any definite object for experiment or observation, we are able to say whether the result of our inquiry has been satisfactory, and whether the object in view has or has not been accomplished.

But this is unfortunately not the case in medicine. There are certain peculiarities necessarily connected with the subject, which render it extremely difficult to appreciate the value of experiment and observation. In our experiments we are seldom able to ascertain with accuracy the previous state of the body on which we operate, and in our observations we are seldom able to ascertain what is the exact cause of the effect which we witness. The history of medicine in all its parts, and especially that of the materia medica, affords ample testimony to the truth of these remarks. In modern times, and more remarkably in Great Britain, no one thinks of proposing a new mode of practice without supporting it by the results of practical experience. The disease exists, the remedy is prescribed, and the disease is removed; we have no reason to doubt the veracity or the ability of the narrator; his favourable report induces his contemporaries to pursue the same means of cure, the same favourable result is obtained, and it appears impossible for any fact to be supported by more decisive testimony. Yet in the space of a few short years the boasted remedy has lost its virtue, the disease no longer yields to its power, while its place is supplied by some new remedy, which, like its predecessors, runs through the same career of expectation, success, and disappointment.

Let us apply these remarks to the case of fever, the disease which has been styled the touchstone of medical theory, and which may be pronounced to be its opprobrium. At the termination of the last century, while the doctrine of Cullen was generally embraced, typhous fever was called a disease of debility, and was of course to be cured by tonics and stimulants. No sooner was it ascertained to exist, than bark and wine were administered in as large doses as the patient could be induced or was found able to take. No doubt was entertained of their power over the disease; the only question that caused any doubt in the mind of the practitioner was, whether the patient could bear the quantity that would be necessary for the cure.

To this treatment succeeded that of cold affusion. The high character and literary reputation of the individual who proposed this remedy, its simplicity, and easy application, the candid spirit which was manifested, and the strong testimonials which were adduced by his contemporaries, bore down all opposition, and we flattered ourselves that we had at length subdued the formidable monster. But we were doomed to experience the ordinary process of disappointment; the practice, as usual, was found inefficient or injurious, and it was after a short time supplanted by the use of the lancet. But this practice was even more short-lived than either of its predecessors; and thus, in a space of less than forty years, we have gone through three revolutions of opinion with respect to our treatment of a disease of very frequent occurrence, and of the most decisive and urgent symptoms.

Are we, then, to conclude that all medical treatment is of no avail? that it is all imaginary or deceptive? We should feel most unwilling to be compelled to form such a conclusion, nor do we conceive that it necessarily follows from the premises; but we think that the facts prove the importance of extreme caution in forming our conclusions, and still more that mere experience, without the due combination of well regulated theory, is a most fallacious guide. What objection can the man of mere experience, the rejecter of all theoretical deductions, urge against the multiplied testimony that is now presented to us in favour of the Homœopathic doctrine? — what answer can be made to the Report that has been recently brought forward by the medical commissioners of Paris on the subject of Animal Magnetism? The conclusion that forces itself irresistibly on the mind is, that no medical testimony is sufficient to establish a fact which is in itself incredible, and that this previous incredibility can only be ascertained by an extensive and accurate knowledge of the functions and properties of the living body, both mental and corporeal, in all its modifications and under all circumstances, and by a correct and careful generalization of the knowledge thus obtained. These considerations, as well as others which will present themselves to the mind of the reader, may be deemed a sufficient reason for our attempting no more than to offer a few general remarks on the state of medical science during the period at which we are now arrived. We shall therefore devote this chapter to some cursory remarks on the practice of medicine as it now exists in the different countries of Europe, as well as on the state of some of the collateral or auxiliary departments, and shall conclude by some suggestions for the best means of promoting its future progress.

The prevailing and predominant feeling of the most enlightened and the most judicious of the

British practitioners during the period referred to, has been to place little value upon theory, and to devote their minds almost exclusively to the observation and collection of facts. There can be no doubt that this is a less injurious extreme than the opposite; but if the statement which has been made above be correct, it will probably be admitted that this system may be carried too far. And the same exclusiveness has also induced them to pay too little attention to some of the collateral departments of science. In pathology and in pharmaceutical chemistry they have been far outstripped by the French, and in physiology by the Germans. But at the same time that we feel it necessary to pass this judgment on our countrymen, we must fully admit that the spirit of rational empiricism, to which we have referred above as the characteristic feature of the Cullenean school, has produced a most beneficial influence on the general state of medical practice. If it has, on some occasions, produced fluctuation of opinion, and on others indecision or inertness, it has tended to sweep away much error, and to purify the science from many of the antiquated doctrines and practices that still maintain their ground among our continental brethren. This is more especially the case with our pharmacopœias, where, if we compare those of London and Paris, we shall be struck with the number of what we conceive to be useless articles that are still retained in the latter, sanctioned by the authority of the scientific and enlightened body of men who compose the medical faculty of the French metropolis. We are, however, indebted to France for the most important improvements which have taken place in pharmaceutical chemistry: by their method of obtaining the proximate principles of various vegetable substances, and the greater precision which they have introduced into the formation of the metallic preparations, they have conferred a great and lasting benefit on the art, which, among all the revolutions of opinions and practices, can never be contravailed.*

But the glory of French medical science is its pathology. We are justly proud of our Hunters, our Monros, and our Baillie; and there are certain individuals among our contemporaries who are emulously treading in their footsteps. But any feeling of national vanity which we might be disposed to indulge, must be effectually repressed when we look at the illustrious band of French pathologists, when we review the labours of Pinel, Andral, Breschet, Broussais, Corvisart, Cruveilhier, Dupuytren, Laennec, Bayle, Louis, Gendrin, Foville, Chaussier,† and others, who have directed their attention more exclusively to pathology; and when we add to these the names of those who are to be regarded more in the light of physiologists, Bichat, Vic-d'Azyr, Cuvier, Richerand, Magendie, Edwards, Dumas, Legallois, Adelon, Desmoulins, Serres, Blainville, Flourens, St. Hilaire, Dutrochet, and others, we must admit that France exhibits an unrivalled assemblage of medical philosophers. From the united labours of such eminent men it is impossible not to anticipate the most important results; but we believe that we are justified in asserting that, so far as the practice of medicine is concerned, the benefit is still rather in anticipation than in existence. With certain exceptions, but these no doubt very important ones, we should characterize the French practice as decidedly less effective than that of our country; dependence is placed on remedies which we conceive to be inert, and much of the dietetic regimen which enters so largely into the treatment can produce no effect in the removal of disease. In short, their "médecine expectante," although it may be a less dangerous weapon in the hands of ignorance or presumption, is, in the same proportion, less powerful and beneficial when under the direction of skill and judgment.

If France is pre-eminent for its pathology, Germany is no less so for its physiology and its anatomy. The names of Camper, Blumenbach, Ludwig, Sömmering, Meckel, Wrisberg, Reil, Tiedemann, Wenzel, Sprengel, Jacobsen, Carus, Pfaff, Oken, Osiander, Ackermann, Rosenmüller, Gmelin, Walter, and Treviranus, [J. Müller, Wagner, Henle, Gerber, Bischoff, Burdach, Valentin,] may be selected from many others as among the most celebrated throughout Europe, and as having made most important additions to our knowledge on the subjects to which they have particularly directed their attention. Yet in Germany as in France, the effect of this scientific cooperation on the practice of medicine is not yet fully experienced. The treatment of disease is perhaps not more effective than in France, while it is still more encumbered with complicated formulæ and with antiquated practices, which in this country have been discarded because they have been found useless or even injurious.‡ Italy, which so long took the lead in all scientific pursuits, now offers the prospect of a splendid ruin, where we occasionally meet with an illustrious name, such for example as those of Scarpa, Caldani, Mascagni, Rolando, Bellingeri, and Tommasini, but where medical science, if it has not retrograded, has at least remained stationary. The practice of medicine has, however, had some zealous cultivators; we have already remarked on the activity with which the Brunonian controversy was pursued, and the excitement which was then produced seems to have had a beneficial effect in rousing the dormant energy of the mind, of which some traces are still visible.

A circumstance which has materially contributed to the improvement of the knowledge of practical medicine is the publication of periodical works, whether in the form of journals or of the transactions of societies. They have brought before the public the daily occurrences and passing

* We have a very learned review of the state of medicine during the earlier part of the present century, from the pen of the celebrated Sprengel. It is peculiarly valuable, from the numerous references which it contains to the writers of Germany, and from the view that it presents of the opinions which prevail in that country. The German physiologists afford a singular admixture of profound investigation and fanciful mysticism.—Ed. Med. Journ. v. xii. p. 385 et seq.

† We may refer our readers for an interesting account of the progress of pathology since the commencement of the present century, to a series of papers in the Archives Générales de Médecine, by *M. Dezeimeris*, t. xxix. et seq.

‡ In speaking of the practical writers of Germany, it would be unjust to omit the name of Frank, and not to acknowledge the obligation which he has conferred upon medical science. Among the pathologists, Hartmann of Vienna and Conradi of Gottingen are perhaps the best known in this country.

events in a commodious and interesting form, and thus by exciting attention to them have tended both to diffuse and to increase our knowledge on these subjects. It is, however, very much to be regretted that so valuable a mode of communication should, in too many instances, be used as the medium of personal animosity, and that what ought to be employed for the promotion of the welfare of mankind should become a vehicle of the basest and the most malignant passions. On this point, as well as on the one referred to above, justice compels us to state that the French metropolis offers us an example by which we might profit, in the number, extent, and general character of its medical periodicals, and the same sentiment leads us to remark that the medical periodicals of London are decidedly excelled by those of Edinburgh and Dublin. Among the published transactions of medical societies, the Medico-Chirurgical may fairly be selected for our approbation; these, in the short space of about twenty-four years, have amounted to eighteen volumes, and have acquired a character which is too well established to require recommendation or sanction.

In connection with their transactions we may mention the effect of the societies themselves, which, when they are confined to subjects of medical science, must be highly beneficial. Perhaps no single institution has contributed more to the improvement of our profession than the Edinburgh Medical Society, which for so long a period has maintained a reputation that reflects the greatest credit, not merely on its members, but even on the university to which it is attached. It is, indeed, a remarkable and an honourable circumstance that an association, principally composed of students and entirely conducted by them, should have proceeded for above half a century in so uniform a course of respectability; that during this period they should have admitted of free discussion without deviating into licentiousness, and that amidst the fluctuations to which such an association must necessarily be subject, successors have at all times been found able to direct its progress and qualified to support its reputation.

Another circumstance to which we must briefly advert, which is both the cause and the consequence of the progress of our art, is the improved state of medical schools of all descriptions, both those attached to universities or to public hospitals, and those conducted by private individuals. By a very singular anomaly it has happened that in this country the highest medical honours have been hitherto conferred by those bodies who did not profess to give the requisite means for their attainment. This circumstance may, indeed, in one point of view be regarded as paying the highest compliment to the English universities; but we believe that a very general sentiment now prevails among their most respectable members that this anomaly ought no longer to be suffered to exist, and that medical honours ought to be bestowed upon those, and those only, who have gone through with what may be considered a sufficient course of preparatory studies, and who are able to give satisfactory proof that they have taken due advantage of the means of improvement presented to them. But whatever may have been wanting in the English universities has been long supplied by that of Edinburgh, and, at a later period, by those of Glasgow and Dublin. The great London hospitals and some of the private schools, especially those of anatomy, have for a number of years possessed teachers of the highest talents and most admirably qualified for their office; but our metropolis could not be said to hold out the means of a complete medical education previous to the establishment of the London University and the King's College. These rival schools, rivals as we trust they will always be only in the talents of their professors and the excellence of their arrangements, have each of them laid down an academical course of medical instruction which appears to be complete in all its parts, and which must have the most salutary influence on the character and qualifications of the future members of the profession.

The perusal of the foregoing pages will, we trust, enable our readers to form a tolerably accurate conception of the progress of practical medicine, of the obstacles which it has had to encounter, of the degree in which it has overcome these obstacles, and of its present state of improvement. This we are not disposed to underrate; but at the same time we must acknowledge, that when we reflect upon the immense mass which has been written on the subject, the result seems scarcely adequate to the labour that has been bestowed. We may, therefore, be pardoned if we offer a very few remarks on the means by which, as it appears to us, the object in view might be more effectually attained.

This, we think, should be attempted precisely upon the same plan as in other departments of science :—in the first place, by a more careful exposition of facts; and, secondly, by a more careful generalization of them. In medicine there are various circumstances which render it less easy to ascertain the facts than in most other cases. These depend partly on the nature of the subject, and partly on the situation and character of the observer. It was the shrewd remark of a learned professor that in medicine there are more false facts than false opinions. On all topics, either historical, scientific, or literary, mankind possess a strong avidity for the marvellous. From the constitution of the human mind, the love of novelty is one great principle by which the attention is excited and the intellectual powers are called into action. Hence, in a rude state of society, nearly the whole art of medicine consists in the dexterous employment of this agent, and hence it is still found the most effectual method of attracting the notice of the multitude, who are incapable of close reasoning or calm investigation.

Perhaps one of the most easy and at the same time the most effective means of counteracting this mischievous influence, would be never to receive the evidence for any medical facts upon the authority of a single individual. They should, if possible, emanate from associated bodies, either from public hospitals, medical schools, or societies, the officers of which may afford their united testimony to the alleged facts. Another point which appears to us of vital importance, and which bears essentially upon every department of medicine, is that nothing should be received without the name of the author. The custom of anonymous writing,

which has of late increased to so great an extent, has produced the most unhappy effects, both on the state of medical science and on the character of its professors; it has given rise to a degraded and depraved taste, no less at variance with honour and honesty than with the spirit of scientific research. We will venture to assert that no man ought to publish any statement or any opinion to which he would scruple to attach his name. It may occasionally happen that an individual of a timid or a modest disposition may, by this restriction, be deterred from detecting an error or controverting a train of false reasoning, but the loss which might by this means be incurred would be amply repaid by the greater authenticity and the greater correctness of our medical publications.

With respect to the second suggestion, the more accurate generalization of facts, when the facts themselves are fully substantiated,—this must be accomplished by the due exercise of judgment and sagacity, and can scarcely be directed by any general rules. We may remark, however, that one obvious mode of attaining this end is to arrange our insulated facts as much as possible in the form of statistical tables, by which we may readily observe their connection with or relation to each other, and may thus be prevented from forming a hasty or unauthorized conclusion, derived merely from single cases or individual observations.

Another important means of obtaining the object in view is to prescrve great precision in the use of technical and scientific terms. How many controversies have occupied the mind for ages, and have filled almost innumerable volumes, which have essentially turned upon the definition of a word? How frequently have remedies been prescribed, not for the symptoms, but for the name of a disease? How frequently has an article of the materia medica been employed, not from an experience of its actual effects, but from some nominal property assigned to it by an imperfect analogy or imaginary quality? The means that have been proposed to check these aberrations, to rectify the above-mentioned errors, and to reduce medical science to its appropriate and correct limits, are indeed few and simple, and not of difficult application. But there is one essential requisite, without which they can be of no avail,—a mind disposed to the reception of truth, determined to follow it wherever it may lead the inquirer, united to a high sense of moral obligation, which may induce the medical practitioner to bear in mind that his profession is a deposit placed in his hands for the benefit of mankind, and that he incurs an awful degree of moral responsibility who abuses this sacred trust, or diverts it to a base or selfish purpose.

J. Bostock.

[Sketch of the state of American Medicine before the Revolution.*—As may naturally be presumed, in a country circumstanced as the American colonies were for a long period after their original settlement, the medical profession continued for a succession of years in a low and degraded condition. In point of respectability, it undoubtedly stood lower than either the legal or theological professions. The persecutions of the mother country had filled the ranks of the latter with men of learning, talents and piety — while the offices of honour and emolument under the crown, offered allurements sufficiently powerful, to induce many who were distinguished in the law to emigrate to this western world. With medicine it was far otherwise. It is only in populous towns and cities that our art can flourish; and the wilds of America, however fragrant they might be with the spirit of freedom, offered no attractions to the medical men of the old world. The advantages attending an emigration were too distant and precarious to warrant such a step; and accordingly for a long time, with some few exceptions, none but those who had failed to attain respectability or employment at home, would venture on so dangerous an experiment. Nor were the young native physicians for a long time calculated to remedy the evil. To become a well-qualified physician, requires a course of study and a variety of observation which was not to be obtained in any of the colonies. There were neither lectures nor hospitals which could be resorted to, while the great expense attending a foreign education put it out of the power of all, except a favoured few, to avail themselves of the only means of becoming regularly instructed. Under such circumstances it was not to have been expected, for a long series of years after the first settlement of the country, that our profession would be at all distinguished for character or knowledge. The progress of civilization, an augmenting population, together with the increasing facilities of European communication, tended gradually to meliorate this condition of things, and for many years preceding the revolution, medicine could boast of not a few names who shed a lustre upon the profession to which they belonged.

With those preliminary remarks, I propose to give a brief sketch of the state of medicine in this country anterior to the revolution; and, for the sake of convenience, shall consider it under the three divisions of *medical practice*, *medical literature*, and *medical institutions*.

Medical Practice. — The earliest practitioners of medicine in this country appear to have been the clergy — this was at least the case in New-England, where, for several years after the first settlement of the colony, the functions of the physician and divine were performed by the same individual. This combination has not been uncommon in the history of the world. In the early dawn of medicine, the priests of Egypt and Greece collected and preserved what was known of the healing art, and in the infancy of every country the same association will probably be found to exist. Nor is it, by any means, an unnatural one. Physical and moral evil are so intimately connected that those who are administering relief to the one, cannot be regardless of the other. Hence, in the absence of the regular physician, the priest appears to be his most proper representative. Besides this, the character of the first emigrants, and the high tone of religious feeling which drove them for an asylum to this western world, continued for a long time to give a preponderating influence to the

* [This article formed the essential part of the annual address delivered in 1842, before the Medical Society of the State of New York, of which Dr. Beck was then president. The address is published in the transactions of the State Society. — R. D.]

clergy, in all the secular as well as religious concerns of the colony. In the annals of the first colonists, accordingly, will be found the names of several clergymen who practised the healing art. Besides these, some of the first governors of the eastern colonies also practised physic. Two of them, of the name of Winthrop, appear to have been particularly celebrated. One of them was Governor of Massachusetts, the other of Connecticut and New Haven. Of the latter, Cotton Mather says: "he was furnished with *noble medicines*, which he most charitably and generously gave away upon all occasions." (Magnalia, p. 31.) He was a member of the Royal Society of London, and some of his communications are to be found in their transactions. Amid such practice, however, as this must necessarily have been, it is easy to conceive that nothing could be done to improve the state of medicine, and that the greatest facilities must speedily have been offered for successful imposition upon the credulity of the public. This supposition is fully confirmed by the fact that so early as the year 1649, a law was passed in Massachusetts, "that no chirurgeons, midwives, physicians, or others, presume to exercise, or put forth any act contrary to the known approved rules of art, in each mystery and occupation, nor exercise any force, violence or cruelty, upon or towards the body of any, whether young or old, (no, not in the most difficult and desperate cases,) without the advice and consent of such as are skilful in the same art, (if any such may be had,) or at least of the wisest and gravest there present, and consent of the patient or patients, if they be mentis compotes, much less contrary to such advice and consent, upon such severe punishment as the nature of the fact may deserve."* This appears to have been the very first attempt of the civil authority, in any of the colonies, to put a restraint upon those who pretended to the practice of physic. Salutary as this law may have been, in some respects, it afforded but a slender protection against the existing deficiencies in the profession. It made no provision for the education of medical men, and it established no test of their qualifications.

The State of New York, I believe, is entitled to the honour of adopting the first effectual measures for regulating the practice of medicine. This was not, however, until so late a period as 1760, when the General Assembly of the Province ordained that "no person whatever should practise as a physician or surgeon, in the city of New York, before he shall have been examined in physic or surgery, and approved of and admitted by one of his majesty's council, the judges of the supreme court, the king's attorney-general, and the mayor of the city of New York, for the time being, or by any three or more of them, taking to their assistance for such examinations such proper person or persons as they in their discretion shall think fit." (Laws of New York, from 1752 to 1762, by Livingston & Smith, vol. ii. p. 198.) If the person so examined was approved, a certificate was given, allowing him to practise physic or surgery, or both, throughout the province. In case of non-compliance, the penalty was a fine of five pounds.

In 1772, a similar law was adopted in New Jersey. These examples were not imitated in the other colonies, where the practice continued unrestrained, and physicians were responsible to no authority for mal-practice. In Connecticut, an attempt was indeed made to effect a reformation in this respect, but so strong was the current of prejudice against the measure, that it completely failed. As far as my investigations have extended, the foregoing is all that was done, or even attempted by the constituted authorities, in behalf of our profession, previous to the Revolution; and it shows conclusively how little its present respectability is owing either to the colonial governments, or to the mother country.

During the period embraced in this sketch, the division of practice into distinct departments, so generally adopted in Europe, was not recognised in this country. Both physic and surgery were practised by the same individuals; besides this, it was the general custom of physicians to prepare and compound their own medicines. In the year 1765, Dr. John Morgan, a distinguished physician of Philadelphia, endeavoured to introduce a change in the existing mode of practice, by recommending a separation of it into the three branches of physic, surgery, and pharmacy, and appropriating each of these departments to a separate class of practitioners. Having spent several years of his life in the acquisition of professional knowledge, in countries where he had seen the practical operation of this system, he became deeply impressed with the importance of it to improve the character of the profession at home. On his return, he accordingly not merely recommended it in a discourse which he published, but adopted it in his own practice. Although in every respect fully accomplished, he consequently declined engaging in any surgical operations, and confined himself entirely to medicine.† Whatever may be thought of the general utility or propriety of such a plan, it was undoubtedly at that early period somewhat premature, and probably did not meet with much encouragement.

Until about the middle of the last century, midwifery was exclusively in the hands of females, and physicians were called in only in preternatural and tedious cases. According to Dr. Bartlett, of Massachusetts, Dr. James Lloyd was the first systematic practitioner in midwifery in that section of the United States. He had enjoyed the instructions of Warner, Sharpe, Smellie, and Hunter, of London, in 1753, and in the following year settled in Boston. (Medical Communications and Dissertations of the Mass. Med. Soc. vol. 2, p. 244.) In 1756, Dr. William Shippen, Jr., on his return from Europe, commenced the same branch of professional business in Philadelphia; and although at this period physicians were scarcely ever employed in natural labours, it is stated by his biographer, Dr. Wistar, that he did away completely with this prejudice,

* General Laws and Liberties of the Massachusetts Colony, in New England, revised and reprinted by order of the General Council, held at Boston, May 15, 1672.

† A discourse upon the institution of medical societies in America, delivered at a public anniversary commencement held in the college of Philadelphia, May 30, 1765; with a preface containing the author's apology for attempting to introduce the regular mode of practising physic in Philadelphia. Philad. 1765.

and in the course of a few years was fully occupied. (Eulogium on Dr. Wm. Shippen. By Caspar Wistar, M. D., Philad. 1818, p. 31.)

These are the two first physicians employed as regular accoucheurs in this country, of whom we have any notice; and they deserve especial commendation, as having led the way in overcoming deep-rooted prejudices, and in transferring to the profession, from the hands of ignorant and uneducated females, the practice of a difficult and delicate art.

From the connection subsisting between the mother country and the colonies, as may naturally be presumed, the same doctrines prevailed in both, and the practice was essentially the same. At the beginning of the eighteenth century, the celebrated Boerhaave commenced his career. Gifted with every endowment, natural and acquired — a mind powerful and generalizing — a fascinating eloquence — learning the most varied and profound, and a character radiant with every virtue, this great man was eminently qualified to take the foremost lead in the medical world. Not merely the age in which he lived bowed at once to the supremacy of his genius, but his doctrines continued to control the opinions and practice of medical men during the larger portion of a whole century. The leading feature in the system of this distinguished theorist, was the great and undue importance which he gave to the fluids in the production of disease. These, according to him, became variously changed, not merely in their physical properties, but in their chemical composition. They became morbidly thick or thin, while they were contaminated by acid and alkaline acrimonies, and various other morbific matters. To such conditions of the fluids, diseases were attributed; and medicines were supposed to act by counteracting and changing them. Such were the doctrines prevalent in the old world during the last century. Their influence was no less undisputed in this country, and the general practice was modified by them. In the management of diseases, medicines were accordingly given with the view of thinning or incrassating the blood, and altering its qualities. Much confidence was placed in the powers of nature, and the results of critical days watched with the greatest anxiety. On these, it was supposed that the *materies morbi* was discharged, and thus the relief of the patient effected. The matter was looked for chiefly in the urine, and, according to Dr. Rush, "glasses to retain it were a necessary part of the furniture of every sick-room." (Rush's Obs. and Inqs., vol. iv. p. 396.) In the treatment of fevers, sudorific medicines were principally resorted to, and to aid their operation, and to facilitate the elimination of the morbid matter, the supposed cause of disease, patients were confined to their beds, and cool air denied them in the most rigid manner. Bleeding was not a general remedy in fever. In yellow fever, so far as we can judge from the opinions of a single individual, it was considered of doubtful and even dangerous tendency. Dr. John Mitchell, a distinguished physician of Virginia, in his account of the yellow fever which prevailed there in the years 1737, '41 and '42, in speaking of this subject, says, "plentiful bleeding is a means commonly found most effectual to obtain this end, (i. e. to ward off local inflammation,) in the benign inflammatory fevers; but we cannot apply this most effectual remedy in this disease, because it evacuates only or chiefly the red globules of the blood, which, as we see by its state taken notice of above, are in too small a proportion already; and bleeding further breaks the texture of the blood, which above all things is to be avoided in this disease; for after plentiful bleeding, the pulse sinks, or at least is so low and feeble about the state of the disease as to prove of dangerous consequence; which some instances I have known seem to confirm." (American Medical and Philosophical Register, vol. iv., p. 198.) He did not, however, discard bleeding altogether. In small quantities, he found it serviceable to prepare the system for other evacuations. The remedies which he principally relied on were sudorifics, but more especially cathartics. Upon the importance of this latter class of remedies, he dwells with peculiar urgency, and many of his views are characterized by great good sense and practical acumen. It was entirely by the observations and suggestions of this physician, that Dr. Rush, as he himself frankly acknowledges, was afterwards led to the free use of purgatives in the yellow fever of 1793.

In relation to yellow fever, the prevalent opinion at this period was, that it was a contagious disease. Both Drs. Mitchell, of Virginia, and Lining, of Charleston, express decided opinions on this subject. Dr. Lining, too, expresses the belief that, like small-pox and measles, it does not attack the second time. It is hardly necessary to state, that the accurate and extended observations of more recent times have completely disproved both these positions. Indeed, if there be any one point in medicine which may now be looked upon as settled, it is that the yellow fever is not a contagious disease; and numerous observations incontestably show that it may assail the human constitution a second time.*

According to Dr. Rush in his account of the state of medicine between the years 1760 and 1766, bloodletting was used plentifully in pleurisies and rheumatism, but sparingly in all other diseases, (Observations and Inquiries, vol. iv. p. 396,) a practice, it must be admitted, much more judicious and safe, to say the least, than the indiscriminate and sanguinary practice which was afterwards adopted by this distinguished theorist. At this period, according to the same authority, some of the most potent and useful articles of the Materia Medica were but partially exhibited, owing to the prejudices of the public, and in some measure to the fears of the physician. Among them were the Peruvian bark and opium, both of which it was necessary to disguise by admixture with other medicines. Blisters were generally used, but their application was confined to the last stages of fevers. Dr. Rush says "wine was given sparingly even in the lowest stages of what were then called putrid and nervous fevers." (Ibid. vol. iv. p. 399.) Nevertheless, I find that so early as 1746 the liberal use of wine in typhus fever was recommended by that distinguished physician,

* [For the conflicting views on these subjects, see FEVER, YELLOW. — R. D.]

Dr. Colden, Lieut. Governor of the colony of New York. In the year just mentioned, a fever of this description prevailed epidemically at Albany, and in many cases proved fatal. "It had the appearance of a remittent, with frequent low pulse, except in the paroxysms, when it was high; a dejection of spirits, great restlessness, an entire prostration of appetite, clammy sweats of a rancid, putrescent smell." By the physicians of the place, it had been treated as an intermittent, but without success. By the advice of Dr. Colden, Madeira wine, to the extent of a wine glass full every four or five hours, was ordered, and with the happiest effects. One patient who recovered, drank a gallon in a few days. In all these cases the wine was given in the last stage of the disease. (Lond. Med. Obs. and Inq. vol. 1, p. 215.)

Although the physicians in the colonies generally followed the prevalent practice of the mother country, yet they are entitled to the credit of originating some modes of practice of great value. The most important of these is the application of mercury in the treatment of inflammatory complaints. This practice took its origin as far back as the year 1736, and the credit of originality is generally conceded to Dr. Douglass, a physician of Boston, by whom it was used in the angina maligna which prevailed extensively over the colonies at that period, and committed the most dreadful ravages. (New England Journal of Medicine, vol. 14, p. 4.) By Dr. James Ogden, a respectable physician of Long Island, this practice was extensively applied in the same disease about the year 1749. (New York Med. Repository, vol. 5, p. 97.) The preparation of mercury which was used was calomel. In consequence of the success which attended the use of this remedy in this disease, it was shortly after resorted to in other inflammatory complaints; and about the middle of the last century, it was in common use in this country in pleurisy, pneumonia, rheumatism, and others of the phlegmasiæ. I am aware that the credit of this practice is claimed elsewhere;* but there can be no doubt that in its origin it is exclusively American, and that to our colonial physicians the world is indebted for one of the greatest improvements ever made in practical medicine.

Among the events which characterized the history of our colonial medicine, the most remarkable, and certainly the most exciting, were those which attended the introduction of the practice of inoculation for the small-pox. This was first introduced into this country in the year 1721; and it is to a clergyman, Dr. Cotton Mather, that the honour belongs of having first recommended it. During this year the small-pox raged in Boston with unparalleled fury and fatality. Dr. Mather having read, in the Transactions of the Royal Society of London, an account of a new mode of mitigating the violence of the disease by inoculation, as practised in Turkey, communicated it to the physicians of the place, and urged their adoption of it. With the exception of one individual, it was unanimously opposed by the faculty. This individual was Dr. Zabdiel Boylston, who, with the confidence of an honest and enlightened mind, commenced his operations on his own children and servants.† The controversies which ensued were of the most ferocious and disreputable character. Such was the tempest of popular indignation raised against the practice, chiefly by the inflammatory conduct of the physicians, at the head of whom was Dr. Douglass, that both Drs. Mather and Boylston were in danger of losing their lives. Passion and prejudice on the one side were, however, met by decision and success on the other; and inoculation, defended by almost all the clergy, many of whom preached and wrote in its defence, soon triumphed over opposition, and became prevalent in Boston and the neighbouring towns. From thence it was introduced into the other colonies, and although uniformly resisted at first, the public mind became gradually reconciled to it. So early as 1738, it was practised in Charleston, S. C. during the epidemic small-pox which then prevailed there. In 1759 it was generally adopted in Philadelphia, where its dissemination was very much facilitated by a defence and recommendation of it by Dr. Redman. The true merit of Dr. Boylston, in relation to the introduction of inoculation, will not be appreciated unless it is stated that at this time the practice had only just found its way into Europe. By a singular coincidence, the first case of inoculation in Europe took place in England in April, 1721, only two months before the first experiment of Dr. Boylston, and entirely without his knowledge. This was the case of the daughter of Lady Wortley Montague. This celebrated female, during her residence in Constantinople, having become acquainted with the safety of the practice, had her son inoculated, and on her return to England, her daughter was subjected to the same operation, and with perfect safety. (The History of the Inoculation of the Small-Pox, &c. By William Woodville, M. D. vol. 1, p. 85.) This led the way to the speedy diffusion of the practice in England, as the experiments of Boylston did in this country. It is gratifying to know, that although opposed and slandered at home, this eminent physician was appreciated abroad. In 1725 he visited England, and was received with the highest favour and attention by the most distinguished characters in the nation, and even by royalty itself. He was elected a fellow of the Royal Society, it being the first instance in which that honour was conferred upon an American.

Among the practices peculiar to the colonies, was the administration of mercury as a preparative to inoculation. By the illustrious Boerhaave, it had before this been suggested that mercury

* Dr. John Armstrong, in his work on Typhus, gives the sole credit of this practice to Dr. Robert Hamilton of Lynn Regis. In another place, I have shown the incorrectness of this statement. (See New York Medical Gazette, No. 1.) From the account of Dr. Hamilton himself, it appears that his attention was not called to the practice until the year 1764; whereas it had been in very general use in this country many years before.

† The first experiments by Boylston were made on the 27th June, 1721, on his own son, thirteen years of age, and two blacks in his own family, one of thirty-six and the other two years of age, and all with success. During the prevalence of the small-pox in that and the following year, he inoculated with his own hand two hundred and forty-seven, of both sexes, from nine months to sixty-seven years of age. Thirty-nine were inoculated by other physicians after the tumult had somewhat subsided, making in all two hundred and eighty-six, of whom only six died. During the same period, 5,759 had taken the natural small-pox, 844 of whom had died. See Thatcher's Medical Biography, p. 163.

would prove an antidote to small-pox; and from him, no doubt, the hint was taken. In 1724, Dr. Huxham also recommended calomel, not merely in the natural small-pox, but also when inoculated. (Woodville's History of Inoculation, vol. 1, p. 342.) It was only in the colonies, however, that the practice was tried on a large scale; and an interesting account of its effects has been left us by Dr. Benjamin Gale, of Connecticut, in a paper published in the Philosophical Transactions for 1765. The credit of the practice is given by him to Dr. Thomas of Virginia and Dr. Munson of Long Island, by whom it was established in 1745. According to the statements of Dr. Gale, it appears that the deaths from the natural small-pox, before inoculation was introduced into New England, averaged 1 in 7 or 8; when inoculation was introduced, the deaths amounted to 1 in 30. By improvements and proper precautions, they were reduced to 1 in 80 to 100; and finally, by preparing the system by the previons use of mercury, the deaths were only 1 in 800 or 1000.*

For the early and prompt investigation, as well as the sound and original views which they advanced in relation to the pathology and treatment of that acute and now well-known disease, croup, our colonial physicians are entitled to the highest applause. Although not unknown or unnoticed previously, the credit is generally conceded to Dr. Home of Edinburgh, of having given the first full description of this disease. This appeared in 1765. In 1771, Dr. Crawford published his "Disquisitio Inauguralis de Cynanche Stridula;" and in 1778 appeared the elaborate work of Michaelis of Gottingen, entitled "Dissertatio Inauguralis de Anginâ Polyposâ sive membranaceâ." These were all the foreign publications which had appeared on this interesting subject. Between the years 1770 and 1781, in this country, Drs. Rush, S. Bard, Chalmers, Middleton and Bayley, all published in relation to it, and by them, especially the two latter, more correct views were enforced than had been entertained by Home and others. Contrary to the opinion of Home, that the secretion of mucus on the inside of the trachea was the cause of the disease, Dr. Bayley established the fact that the disease was an inflammation of the mucous membrane of the trachea, and that the effusion and false membrane were the consequences of this inflammation. Based upon the idea that it was an acute and rapid inflammation, the treatment recommended was of the most decided character. Bloodletting ad deliquium—the free use of tartar-emetic, at first to produce vomiting, and then to keep up nausea, together with the free use of calomel, were all originally recommended by them, although the credit of every one of them has since been claimed by others.† In determining the true nature of this disease, as well as the treatment most efficacious, the merit of Bayley stands pre-eminent, and the tract which he has left on this subject, is sufficient of itself to establish his reputation as an original observer, and an able and accomplished practitioner.‡

If we may believe the authority of Dr. Douglass, who wrote about the year 1753, and of Smith, the historian of New York, the general character of the profession could not have been very elevated, and quackery must have flourished in great perfection. Smith says, "few physicians amongst us are eminent for their skill. Quacks abound like locusts in Egypt, and too many have recommended themselves to a full practice and profitable subsistence. This is the less to be wondered at, as the profession is under no kind of regulation." (History of New York, by William Smith, A. M. p. 326.) That in a state of

* Historical Memoirs, relating to the practice of Inoculation for the small-pox, in the British American Provinces, particularly in New England. By Benjamin Gale. See Philosophical Transactions, abridged, vol. 12, p. 229.

† As a sample of the manner in which practices originating in this country, are appropriated abroad, not from design, but ignorance, the following may be adduced. Dr. Stokes, in his recent and invaluable treatise on diseases of the chest, in speaking of tartar-emetic in croup, holds the following language: "For the introduction of this inestimable remedy in the treatment of the croup, the science is indebted to Dr. Cheyne. In his Essay on Cynanche Trachealis, published in Edinburgh in 1801, we find the treatment recommended; and it is no small evidence in its favour, that in the year 1832, after an experience greater than falls to the lot of most men, the opinions of this philosophical investigator of disease have remained unaltered. How changed would be the character of medicine, if, in support of many of our remedies, there could be brought forward such evidence, and such an advocate!" p. 144, Amer. Ed. Dr. Bayley recommended and used the same remedy, in the same way, and with the same objects in view, a quarter of a century before.

‡ Cases of Angina Trachealis, with the mode of cure: in a letter to William Hunter, M. D. &c. By Richard Bayley, Surgeon. Printed, New York, 1781. For the purpose of showing the views of Bayley in relation to the nature and cure of this disease, I shall quote the following from his paper. "When the Angina Trachealis is theoretically considered, there will probably be formed (as is generally the case when facts are not ascertained) opinions as various as the information and different faculties of men may suggest. I am induced to adopt the following: That the larynx, aspera arteria, and bronchial pipes have one common membrane, which, we are informed by injection, consists of little more than an infinity of blood-vessels, and consequently liable to *inflammation*, as all vascular parts are. An increased action of these vessels (as in pleuritic and puerperal fevers) occasions a preternatural secretion of lymph, which, from the ingress and egress of the air, becomes condensed, and assumes the appearance of a membrane, and its compactness will depend on the age and habit of the patient and the state of the atmosphere.

"The common opinion is, that those who die of this complaint are suffocated by the membrane's closing the wind-pipe. Another more respectable opinion is, that a spasm of the muscles of the larynx closes the scene. The circumstances which precede *death* in this disease, compared with those appearances which have regularly taken place in the cases which I have seen *successfully* treated, sufficiently explain the cause of the patient's death from the laws of the blood's circulation. To preserve the healthful state of an animal, it is necessary that the whole mass of blood should circulate through the lungs in a given time, and the free admission and expulsion of air contributes to this regular process; the change, also, which gradually takes place in the lungs, seems more directly to account for the swelled face, tumid jugulars and the full staring eyes, which are symptoms that accompany the progress of this complaint and add to this, the larynx, aspera arteria and bronchia have been found pervious in every subject I have dissected, while the ramifications have been as regularly filled with a glairy mucus.

"From what precedes, it is obvious that the angina trachealis is considered as an *inflammatory disease*, the treatment of which must vary in every degree, according to its violence: and though the common antiphlogistic treatment will in some cases relieve, if early applied, yet the most desperate may yield to *repeated bleedings ad deliquium* from the jugulars, the free use of *tartar-emetic* and other evacuants, with a *large blister* covering the larynx and aspera arteria, while the mucus filling up the ramifications of the bronchia may be emptied by the action of vomiting." See New York Medical Repository, vol. 14, p. 346. Although not published until the year 1781, the paper of Bayley contains the result of his observations and practice for a number of years previously.

society where the means of medical education were so scanty, and where no laws existed to regulate the profession or restrain admission into its ranks, quackery should be very rife, is certainly by no means singular. It would be unjust, however, to suppose that it is peculiar to such a state of society, or even that it prevailed to a greater extent than it does in the present day. Mortifying as it is, it is, nevertheless, a fact that it is peculiar to no particular age, or country, or state of society. It has existed from the earliest periods, and will continue to exist as long as human beings are found upon the face of the earth. The rude savage and the polished citizen are equally its victims, and civilization and refinement only render its forms more complicated and insidious. At no period in the history of this country, it may safely be asserted, has empiricism flourished to the same fearful extent as at the present time, notwithstanding our boasted improvements in other respects. Assuming a thousand different disguises, it is, in many high places in our country, sapping the very honour of the profession, and corrupting it to the core. Notwithstanding the prevalence of quackery in the colonies, it does not appear that the well-educated part of the profession lent it any countenance, and it would be well if the same could be said in the present day. A recollection of these facts should therefore moderate somewhat the severity of our judgment in relation to the state of our colonial medicine, at the same time that it should excite us to renewed diligence in endeavouring, if possible, to correct existing abuses.

II. *Medical Literature.*—I come next to take a brief notice of the state of medical literature previous to the revolution. Although not abounding in materials of very high interest or importance, the medical literature of this period is by no means contemptible. In forming a judgment in relation to it, we should recollect the circumstances in which the American physician was placed, and the slender inducements which were held out to undertake the labours of authorship. The two great motives which induce men, in any age, to write — the love of literary distinction, and the hope of pecuniary gain, then exercised but a feeble and limited influence; and accordingly, the colonial physicians only turned authors on some special emergency of public duty, or for the purpose of promulgating and enforcing some new and useful mode of practice. The capabilities of our early physicians, therefore, ought to be judged of, not so much by the quantity, as by the quality, of the productions which they have left us; and an impartial review of them will show us that they do not suffer by a comparison with the productions of their European brethren at the same period. Some of them were not thought unworthy of being published in the Transactions of the Royal Society, while others found a place in the publications of the learned medical associations of the day, in the mother country.

A brief review of what appeared in the colonies, will be, not merely interesting, as a matter of historical record, but will furnish the best evidence of the general drift and progress of medical mind during this period.

The earliest medical publications appeared in Massachusetts, and were called forth by the prevalence of epidemic diseases; and the first appears to have been a tract by Thomas Thatcher, a clergyman and physician, of Massachusetts. It was entitled "A Brief Guide in the Small-Pox and Measles," and was published in the year 1677. Cotton Mather, in his Magnalia, gives the life of this person, and represents him as a man of learning and ingenuity.

In 1721, Benjamin Colman, a minister of Boston, printed a small pamphlet entitled—"Some Account of the New Method of Receiving the Small-Pox, by Ingrafting or Inoculating;" in which he defends the practice of inoculation, which had just been introduced by Dr. Boylston.

Five years after this, Dr. Boylston, while on his visit to England, published there, at the request of the Royal Society, "An Historical Account of the Small-Pox, inoculated in New England." In the following year it was reprinted in Boston.

In addition to the above may be mentioned the names of Thomas Howard and Nathaniel Williams, both of whom were clergymen as well as physicians. The former wrote a Treatise on Pharmacy, in 1732; and the latter a pamphlet "On the Method of Practice in the Small-Pox in 1730."

The most voluminous writer, however, who appeared at this period, was Dr. William Douglass. He was a native of Scotland, and emigrated to New England about the year 1716. Although a man of talent and learning, he appears to have been of an unhappy temper of mind, to which he gave loose in many of his writings. He was a most virulent opponent of the practice of inoculation, and did all in his power to excite popular indignation against it. Besides several publications on this subject, he has left a tract on the putrid sore throat distemper which prevailed epidemically in the colonies, entitled—"The Practical History of a New Epidemical Eruptive Miliary Fever, with an Angina Ulcusculosa, which prevailed in New England in 1735 and '36." This was published in 1736, and is in every respect a paper of great value. Besides giving the fullest account that we have of this dreadful epidemic, it contains the first suggestion in relation to the use of calomel as a remedy. This essay has recently been reprinted in the New England Journal of Medicine and Surgery, vol. xiv. p. 1. The most elaborate work, of this author was "A Summary, Historical and Political, of the First Planting, Progressive Improvements, and Present State of the British Settlements in North America." This was published in 1760, and contains some amusing notices of the state of the profession in the colonies.

These were pretty much all the medical writers of whom Massachusetts could boast for upwards of a century and a half.

In the middle and southern colonies, medicine appears to have been cultivated with much more success than in the eastern. This may be accounted for by the fact that the former enjoyed the services of several foreign physicians, who had early emigrated thither, enriched by the best medical education which Europe could afford. It appears also to have been more common with them

to send their young men to foreign universities to complete their medical studies. In addition to all this, a taste for researches in natural history began to develop itself much sooner in some of the southern colonies, and doubtless produced a salutary effect in spreading the influence of liberal sentiments. To these causes is to be attributed the early superiority of the southern colonies more especially.

Of the colonial physicians none were more active or distinguished than those of South Carolina. In 1734, a native of this state, William Bull, obtained a degree in medicine, at the University of Leyden, and on that occasion, defended and published an inaugural dissertation, "De Colica Pictonum." He had studied under Boerhaave, and seems to have commanded the respect of his associates. By the celebrated Van Swieten, he is spoken of in his commentaries as the *very learned* W. Bull.* In 1749, John Moultrie received the degree of doctor in medicine, at the University of Edinburgh, and published a thesis, "De Febre Flavâ." He was the first native Carolinian who obtained this honour at that university. According to Dr. Ramsay, ten other native Carolinians obtained the same honour, between the years 1768 and '78. (Ramsay's Review of Medicine in the 18th century. New York Medical Repository, vol. iv. p. 398.) As more particularly distinguished in this section of the country, the names of Drs. Lining, Chalmers and Garden, deserve to be especially noticed. They were all natives of Scotland, and emigrated in the earlier part of the last century. Being men of unquestioned abilities, learning and enterprise, they contributed greatly, both by their influence and writings, to elevate the character of the profession. To Dr. John Lining, we are indebted for some of the most valuable statical experiments ever published. They were continued throughout the whole of the year 1740. He ascertained his weight in the morning and evening; the weight of the food which he swallowed, and the weight of the urine and alvine excretions ejected. The result of these troublesome experiments was published in 1743, in the Transactions of the Royal Society of London. (Vol. xlii. p. 491. Thomson's History of the Royal Society, p. 129.) In 1753 he published "A Description of the American Yellow Fever," in a letter to the celebrated Dr. Robert Whytt, professor of medicine in the University of Edinburgh. This was the first account of this terrible disorder which had emanated from this continent, and stands to this day unrivalled for the general accuracy and minuteness of its description. (Edinb. Essays and Obs. vol. ii. p. 370.)

To Dr. Lionel Chalmers we are also indebted for several valuable productions. In the year 1754 he communicated to the Medical Observations and Inquiries of London, a paper on the *Opisthotonos and Tetanus*. These appear to have been very prevalent, at that time, in Charleston, and Dr. Chalmers seems to have had a large experience in them. The remedies which he principally recommends are, bloodletting in the commencement, the warm bath, the free use of opium and emollient enemata. (Vol. i. p. 87.) In 1768, he published "An Essay on Fevers," in which he enters into an extensive discussion of the theory of febrile diseases, and proposes a new method of treating them. Contrary to the prevalent belief of the time, Dr. Chalmers endeavours to show that the cause of fever is not to be sought for in the fluids, but in the solids, and he considers the immediate cause to be "a spasmodic constriction of the arteries and other muscular membranes." Whatever can give much pain or stimulate the nerves so as to cause them to excite such constrictions, he thinks may bring on fever. As an inevitable consequence of this spasm and constriction, irregular distributions of blood take place, producing engorgements of the different viscera, and to this irregular circulation are owing all the phenomena of fever. Spasm of the extreme arteries and irregular distribution of the blood being the leading features of fever, he recommends two indications in the treatment. First, to relax the spasm—second, to relieve the internal fulness of the system; and the two agents which he recommends for accomplishing these purposes are, sweating and purging. Such is a very brief account of his theory of fever, which he supports with much talent and learning. The whole work displays a compass of observation, and a power of theoretical discussion, which should have raised its author to a higher rank than he seems to hold in the lists of medical fame. To perfect originality, the theory of Dr. Chalmers can lay no claim. The doctrine of spasm had been previously suggested by the celebrated Hoffmann, from whom both Chalmers and Cullen doubtless borrowed it. Whether Chalmers was at all indebted to Cullen for any of his views on this subject, it is not easy to say, although it seems very improbable, the essay of Dr. Chalmers having appeared several years before the "First Lines" of Dr. Cullen were presented to the public. Besides this, Dr. Chalmers was the author of an extensive and valuable work on the climate and diseases of South Carolina, in two volumes.† He also recorded and published an important series of meteorological observations at Charleston, continued for ten years, i. e., from 1750 to 1760.‡

Dr. Alexander Garden was another distinguished physician of Charleston at this period. From all the accounts which we have left of him, he appears to have been a man not merely thoroughly versed in his profession, but highly accomplished in literature and general science. He was much devoted to natural history; and the Transactions of the Royal Society contain several of his papers on this department. As a proof of the high estimation in which he was held, it may be mentioned, that Linnæus, with whom he corresponded in Latin, gave the name of Gardenia (in honour of him) to "one of the most beautiful flowering shrubs in the world." He was a member of the Royal Societies of Upsal and of London. The

only medical production which he has left, is an account of the anthelmintic properties of the *Spigelia Marilandica*, together with a botanical description of the plant.*

Virginia could also boast of some distinguished men in the profession; and among these especially were Clayton and Mitchell. Dr. John Clayton was of English origin, and came to Virginia about the year 1705. (Thatcher's Medical Biography, p. 224.) He was particularly eminent as a botanist, and devoted a long life to the investigation of the plants of Virginia. As the result of his labours, he published in 1743 a *Flora Virginica*. It was afterwards republished by Gronovius at Leyden, in 1762.† Besides this, he published in the Philosophical Transactions several papers in relation to the culture of the different varieties of tobacco, together with a full account of the medicinal plants of Virginia. The celebrated author of the Notes on Virginia has left the following respectful testimony to the character of this eminent naturalist and physician: "This accurate observer was a native [incorrect] and resident of Virginia, passed a long life in exploring and describing its plants, and is supposed to have enlarged the botanical catalogue as much as almost any man who has lived." (Notes on Virginia, by Thomas Jefferson, p. 63.)

Dr. John Mitchell was another Englishman who emigrated to Virginia about the beginning of the last century, and no less distinguished for his attainments in medicine and natural history. The productions by which his name has been handed down to posterity are, "An Essay on the Causes of the Different Colours of People in Different Climates," and "Letters on the Yellow Fever of Virginia." The first of these is a production of no ordinary character. It was published in the Philosophical Transactions of 1743, and occupies about fifty pages. The first part of this paper is occupied with the consideration of the cause of the colour of the skin generally, and he endeavours to establish the following propositions: 1. That the colour of white people proceeds from the colour which the epidermis transmits; that is, from the colour of the parts under the epidermis, rather than from any colour of its own. 2. That the skins of negroes are of a thicker substance and denser texture than those of white people, and transmit no colour through them. 3. That the part of the skin which appears black in negroes is the corpus reticulare cutis, and external lamella of the epidermis; and all other parts are of the same colour in them with those of white people, except the fibres which pass between these two parts. 4. That the colour of negroes does not proceed from any black humours or fluid parts contained in their skins, for there is none such in any part of their bodies, more than in white people. 5. The epidermis, especially its external lamella, is divided into two parts by its pores and scales, two hundred times less than the particles of bodies, on which their colours depend. Having established these propositions by a series of facts and reasonings, he comes to the conclusion that the proximate cause of the colour of negroes is three-fold, viz.: the opacity of their skins, proceeding from the thickness and density of their texture, which obstructs the transmission of the rays of light from the white and red parts below them; together with their greater refractive power, which absorbs those rays, and the smallness of the particles of their skins, which hinder them from reflecting any light. The difference thus depending upon a difference in the texture of the skin, he next proceeds to show that the different colours of the human race can readily be explained by the effect of climate and mode of life, in modifying the texture of the skin. He supports the scriptural doctrine of the common origin of man, and thinks the primitive colour was a medium between white and black; "from which primitive colour the Europeans degenerated as much on the one hand as the Africans did on the other: the Asiatics,—unless, perhaps, where mixed with the whiter Europeans,—with most of the Americans, retaining the primitive and original complexion.‡ Such is a brief account of this most ingenious and elaborate paper. Any analysis of it, however, must do it injustice. To appreciate the philosophical acumen and learning which it displays, it ought to be read at full length.

Another paper by Dr. Mitchell is an account of the yellow fever which prevailed in Virginia in 1741, of which I have already had occasion to speak in a previous part of this discourse. This was not published at the time, but the manuscript fell into the hands of Dr. Franklin, by whom, a short time before his death, it was given to Dr. Rush. It has since been published in Coxe's Medical Museum, and in the Medical and Philosophical Register of New York. (Two Letters, vol. iv. pp. 183, 383.)

Another physician of Virginia, and a native, Dr. John Tennent, deserves to be mentioned, as having written the first account of that valuable medicine, the *Polygala Senega*. By him it was used freely, after depletion, in pleurisy and peripneumony, and, as he states, with great success. This appeared in 1736. (See Edinburgh Medical Essays and Observations, vol. v. p. 376.)

Among the medical men of Pennsylvania, there are several who are entitled to notice, as having contributed to the colonial literature of our profession. In 1740 Dr. Thomas Cadwallader, of Philadelphia, published "An Essay on the Iliac Passion," in which he exposes the absurdity of the practice then in vogue, viz.: that of treating it by quicksilver and drastic purges. He recommends in their stead, mild cathartics, with the occasional use of opiates. (Miller's Retrospect of the Eighteenth Century, vol. i. p. 317.) By Dr. Thomas Bond, an eminent physician of Philadelphia, two communications were published in the London Medical Observations and Inquiries, one an account of a worm bred in the liver, (Vol. i. p. 68,) 1754; another on the use of bark, in scrofulous cases, 1759. (Vol. ii. p. 265.) The men, however, who were particularly distinguished, in Phi-

ladelphia, for their zeal in the cause of medical science, were Drs. John Morgan and William Shippen, both natives of that place, and the founders of the first medical school established in this country. Dr. Morgan, after studying medicine at home, went to Edinburgh, where he received the doctor's degree, on which occasion he published an elaborate thesis on the formation of pus—"Tentamen Medicum de Puris Confectione, Edinburgh, 1763." In this dissertation he maintained the doctrine that *pus is a secretion*, prepared by a peculiar action of the secretory vessels of the part. The credit of originality, as it regards this doctrine, has generally been awarded to the celebrated John Hunter. The evidence, however, appears to be conclusive that he was anticipated by Dr. Morgan.* After receiving his degree at Edinburgh, he travelled for some time on the continent, industriously engaged in acquiring knowledge, and everywhere received with the highest honour. As a proof of the estimation in which he was held abroad, it is only necessary to state, that on his return home, in 1765, he was a fellow of the Royal Society of London, corresponding member of the Royal Academy of Surgery of Paris, and licentiate of the Royal Colleges of Physicians of London and Edinburgh. Notwithstanding his devotion to science, Dr. Morgan was not a prolific author. Besides his Thesis, all that we have left is his "Discourse," already noticed, "On the Institution of Medical Schools in America," in 1765, and "A Recommendation of Inoculation, according to Baron Dimsdale's Method," 1776.

Dr. Shippen was born in 1736, and about the year 1760 took his degree at Edinburgh, on which occasion he wrote and published a thesis, "De Placentæ cum Utero Nexû." Besides this, I do not know that he published any thing, but he is greatly and justly celebrated as the first person who lectured on anatomy in this country.

Last, though not least, the contributions of the eminent men who adorned our profession in New York, require to be briefly commemorated. Among these, the first place is unquestionably due to Cadwallader Colden. He was a native of Scotland, and received his education at the university of Edinburgh. In 1718, he settled in New York. He soon, however, relinquished the practice of physic, and became a public character, holding in succession the offices of surveyor-general of the province, member of the council, and finally lieutenant-governor. Although thus withdrawn from the profession, he did not lose his fondness for medical and philosophical pursuits. Among his medical productions is an "Account of the Climate and Diseases of New York." This was published when he was surveyor-general of the province, about the year 1720. It is an exceedingly interesting paper, giving as it does the only account we have of the climate and diseases of this city, at so early a period. In relation to consumption, now so fatally prevalent, he makes the following interesting remarks: "The air of the country being almost always clear, and its spring strong, we have few consumptions, or diseases of the lungs. People inclined to be consumptive in England, are often perfectly cured by our fine air, but if there be ulcers formed, they die in a little time." (Medical and Philosophical Register of New York, vol. i. p. 309.) He also wrote "Observations on the Fever which prevailed in the City of New York in 1741–2," in which he made a number of valuable suggestions in relation to the draining and purification of the city, with the view of preventing the recurrence of the disease. (Ibid, vol. i. p. 324.) Besides these he published a treatise "On the Cure of Cancer," another "On the Virtues of the Great Water Dock," (Ibid. vol. i. p. 300); also, a letter on the "Sore Throat Distemper, which prevailed epidemically in this country," in 1735. (London Med. Obs. and Inq. vol. i. p. 215.) Dr. Colden also pursued the study of botany with great assiduity. He described between three and four hundred American plants, which were afterwards printed in the Acta Upsaliensia. In honour of his daughter, who imbibed the ardour of her parent in this science, Linnæus named a plant of the tetandrous class, that was first described by her, *Coldenia*.

Dr. John Bard was long an eminent practitioner of New York. His professional writings, however, are few. They are—"A Case of Extra-Uterine Fœtus," published in 1760, in the London Obs. and Inq. (vol. ii. p. 369); several papers on the nature and character of the yellow fever, and "An Essay on the Nature and Cause of the Malignant Pleurisy," which proved so fatal to the inhabitants of Huntington and some other places in Long Island in the winter of 1749. (Med. and Philos. Register, vol. i. p. 409.)

Of the physicians of New York, none were more distinguished for their learning and ability, than Dr. Peter Middleton. On the formation of the medical school in New York, he was appointed professor of the theory of physic. At the opening of the school, in 1769, he delivered a discourse in which he took an extensive survey of the state of medicine among the different nations of the globe. This production was afterwards published, and affords ample proof of the learning and ability of the author.† He also wrote a valuable practical letter on the "Croup," already alluded to.‡

Dr. John Jones was a native of Jamaica, Long Island, and was born in 1729. Having acquired the elements of his profession at home, he repaired to Europe, and enjoyed the advantages of tuition under the most renowned men of our profession at London, Leyden, Paris, and Edinburgh. On

* See Cullen's First Lines, edited by Professor Charles Caldwell, vol. i. p. 225, note by Prof. Caldwell. Dr. James Curry, lecturer at Guy's Hospital, also gives the credit of priority to Dr. Morgan, and he adds: "I could not avoid giving that merit to Dr. Morgan, who discussed the question with great ingenuity, in his Inaugural Dissertation, on taking his degree at Edinburgh, in 1763; whilst I could find no proof that Mr. Hunter had taught, or even adopted, such an opinion, until a considerably later period." See Lond. Med. and Phys. Journal for 1817; also New England Journal of Med. and Surg. vol. vi. p. 404.

† A Medical Discourse or an Historical Inquiry into the Ancient and Present State of Medicine; the substance of which was delivered at the opening of the medical school in the city of New York: by Peter Middleton, M. D. and Prof. of the theory of physic in King's College: New York, 1769, pp. 72. A copy of this is in possession of the writer.

‡ This letter was published in 1780, and addressed to Dr. Richard Bayley. In it, he sanctions the practice of Dr. Bayley, as confirmed by his own experience. See New York Med. Repository, vol. xiv. p. 347.

his return to his native country, he speedily rose to the highest eminence. As a surgeon, he undoubtedly stood first in this country. In 1768 he was selected to fill the honourable station of professor of surgery in the medical school of New York, and ranked high as a teacher. The only work of any consequence which he has left us is a volume upon wounds and fractures, published in 1776.* A new edition of this work was printed in 1795, with memoirs of the author, by James Mease, M. D., of Philadelphia. Besides this, there is an interesting paper "On Anthrax," by Dr. Joncs, in the first part of vol. i. of the Transactions of the College of Physicians of Philadelphia.

Before closing this account of our colonial medical literature, it would be unjust not to notice the Transactions of a Society, which contributed in no small degree to raise the scientific character of the country. I mean, the American Philosophical Society. The first volume of their proceedings was published anterior to the revolution, and contains some papers on important medical subjects. It may be stated, too, that four American physicians were elected fellows of the Royal Society of London, before the revolution. These were, Drs. Boylston, Mitchell (of Virginia), Garden, and Morgan. Besides these there were ten other Americans who had been raised to the same honour, viz: four of the name of Winthrop, Paul Dudley, President Leverett, Thomas Brattle, Cotton Mather, Benjamin Franklin, and David Rittenhouse. (Ramsay's America, vol. i. p. 271.)

No medical journal of any description appears to have been published until after the war of our independence, and the only inaugural dissertation that was published was from the New York College, in 1771, by Samuel Kissam, M. D., on the Anthelmintic Virtue of the *Phaseolus Zuratensis Siliqua Hirsuta*, or Cow-Itch, a copy of which may be seen in the library of the New York Historical Society.

III. *Medical Education and Institutions.*—Under this head may be embraced all those acts and establishments of the colonial governments, whose object was the preservation of the public health, as well as those institutions of a public nature, which originated from the combination of individual enterprise and liberality.

From the commercial character of the country, it may readily be supposed, that our first medical establishments were lazarettos, or hospitals intended for the reception of seamen and others infected with contagious disorders. Accordingly we find a hospital of this description established by Massachusetts, nearly one hundred and fifty years ago, at Rainsford island, in the harbour of Boston. Another was at an early period erected on State island in the Delaware, and appropriated to similar purposes for the port of Philadelphia. After the practice of inoculation had become settled, hospitals were gradually established in different parts of the country, for the purpose of carrying patients through this process. Several of this description were in existence shortly after the middle of the last century. These were, however, entirely the result of private enterprise, without any legislative aid, and were, therefore, only of temporary duration. Among the physicians who devoted themselves to this kind of business, Dr. Barnet of New Jersey seems to have been the most conspicuous. Useful as the foregoing institutions undoubtedly were, they could not have produced any effect of consequence upon the existing state of medical science. In 1750, a project of a higher order was set on foot in Philadelphia; this was the establishment of a hospital, upon the plan and embracing all the advantages of the European hospitals, and the individual with whom it originated was Dr. Thomas Bond. No sooner was the object proposed to the citizens of Philadelphia, than measures were adopted to carry it into execution. For that purpose, a petition was presented to the Assembly of the colony soliciting the aid of that body, the result of which was a grant of £2000, on condition that an equal sum should be raised by subscription. The proposed amount was speedily raised; and early in the year 1752, patients were admitted into a building which had been procured for their temporary accommodation. The erection of the present building was not commenced until 1755. In the year 1769, a similar project was started in New York, and the credit of first suggesting it is due to the late Dr. Samuel Bard. In consequence of a public discourse delivered by him, a general interest was excited in the measure.† The liberal contributions of the governor of the province, (Sir Henry Moore,) the corporation of the city, and the legislature of the province, enabled the governors to commence the erection of the building in 1773. After being nearly completed, it accidentally took fire, and was nearly consumed, in 1775. The present building was not completed until 1791, when it was opened for the reception of patients. (An Account of the New York Hospital, 1811.) These were all the hospitals that were attempted anterior to the revolution.

Among the most singular features connected with the history of our colonial medicine, is the fact that so little attention was paid to professional education. This is the more remarkable, inasmuch as our colonial ancestors were fully alive to the importance of general instruction, and the most honourable efforts were made to establish it

* Plain Concise Practical Remarks on the Treatment of Wounds and Fractures; to which is added an Appendix on Camp and Military Hospitals. Principally designed for the use of young military and naval surgeons in North America: by John Jones, M. D., professor of surgery in King's College, New York: pp. 114—Philadelphia, 1776.

† The agency of Dr. Bard is mentioned in the following terms by Dr. Middleton, in his Discourse delivered 1769. "The neccssity and usefulness of a public infirmary, has been so warmly and pathetically set forth in a discourse delivered by Dr. Samuel Bard, at the commencement in May last, that his excellency Sir Henry Moore immediately set on foot a subscription for that purpose, to which himself and most of the gentlemen present liberally contributed. His excellency also recommended it, in the most pressing manner, to the Assembly of the province, as an object worthy of their attention; and the corporation of the city have given assurance of granting a very valuable and commodious lot of ground for erecting the building upon; so that there is now almost a certain prospect of this benevolent and humane foundation soon taking place; and as it is to be on the most catholic and unexceptionable plan, it is to be hoped that it will meet with the countenance and encouragement of every compassionate and good member of society, whatever party or denomination he may choose to be distinguished by on other occasions." Note, p. 60.

on a respectable foundation. So early as the year 1638, Harvard University, in Massachusetts, was founded. In 1691, William and Mary College, in Virginia; in 1700, Yale College, in Connecticut; and in 1746, Princeton College, in New Jersey, were severally established; yet in none of them was any provision made for instruction in medical science. With the single exception, too, of New York, already noticed, and that so late as 1760, the law imposed no qualifications upon those who entered the profession, nor were they subjected to any examinations. The education of physicians, therefore, at this period, restricted as it was to the personal instruction of those with whom they studied, must have been limited indeed. The only mode of supplying this deficiency, was by resorting to foreign countries; and it appears that almost all the distinguished physicians who flourished anterior to the revolution, had received their education in Europe. It is a fact certainly highly honourable and worthy of record, that Harvard College no sooner began to send forth her graduates, than some of them found their way to foreign universities, where they obtained the degree of Doctor of Medicine. In 1642, Samuel Bellingham graduated at the first commencement at Harvard, and shortly afterwards obtained a doctor's degree at Leyden. In 1650, John Glover and Leonard Hoar left the college, and were afterwards honoured with the doctorate abroad, the former at Aberdeen, the latter at Cambridge in England. Hoar afterwards became president of Harvard College. In 1674, Edmund Davie graduated, and subsequently was made an M. D. at Padua. (See the Catalogue of the Graduates of Harvard College.)

As may be supposed, this practice became more and more common, till the period of the revolution; and this, together with the number of foreign physicians of talent and education who emigrated to this country, tended, in no inconsiderable degree, to correct the deficiencies of domestic instruction. The first attempt at establishing a regular system of medical instruction in this country, was not made until a very few years before the revolution; and for this we are indebted to Drs. William Shippen and John Morgan, both natives of Pennsylvania, who projected the plan during the prosecution of their studies abroad. In 1762, Dr. Shippen returned to his native country, and in the year delivered a course of lectures of anatomy to a class of students amounting to twelve in number. These lectures were repeated in 1763 and '64. In the following year Dr. Morgan, who had just returned from Europe, pronounced "A Discourse upon the Institution of Medical Schools in America," before the trustees of the college, in which he proposed a plan for teaching the different branches of medicine, and portrayed with prophetic ardour the blessings which would flow from such a measure. Happily he spoke to a body of men capable of entering into his expanded views; and measures were soon after adopted for forming a medical faculty. Dr. Morgan was appointed professor of the theory and practice of medicine, and Dr. Shippen professor of anatomy and surgery. The other stations were not immediately filled. In 1768, Dr. Adam Kuhn, a pupil of Linnæus, who had just returned to his native country, was chosen professor of botany and materia medica; and in 1769, Dr. Rush, who had just finished his education at Edinburgh, was chosen to the chemical chair. At the same time, Dr. Thomas Bond gave clinical lectures at the Pennsylvania Hospital. Being thus provided with professors on the most important branches of medicine, the school went into complete operation, and the lectures were continued to the year 1775, when they were suspended by the war of the revolution. Dr. Shippen at this time had delivered fourteen courses, and the annual number of students had increased to between thirty and forty. (Eulogium on Dr. William Shippen, by Caspar Wistar, M. D. p. 27, 1818.)

New York soon became emulous of the example set her by Philadelphia, and in 1768 adopted measures for extending similar advantages to medical students. A full medical faculty was regularly organized under the superintendence of the trustees of King's (now Columbia) College, of which Samuel Clossey, M. D. was professor of anatomy, John Jones, M. D. professor of surgery, Peter Middleton, M. D. professor of physiology and pathology, James Smith, M. D. professor of chemistry and materia medica, John V. B. Tennent, M. D. professor of midwifery, and Samuel Bard, M. D. professor of the theory and practice of physic. At the opening of the school, a learned discourse, already noticed, was delivered by Dr. Middleton. A measure so honourable to those immediately concerned in effecting it, and to the city itself, promised not merely to elevate the character of our profession, but to be productive of general good to the community. The fair prospects thus anticipated, were all arrested by the war.

The schools thus started in Philadelphia and New York, were the only ones attempted before the Revolution. The first medical degrees were given by the college of New York. In 1769, the degree of Bachelor in Medicine was conferred upon Samuel Kissam and Robert Tucker. In 1770, the degree of Doctor in Medicine was conferred upon the last of these gentlemen, and in May of the following year, upon the former. In June, 1771, the degree of Doctor in Medicine was conferred on four students, by the Philadelphia college, being the first given by that institution.

With regard to the works that were commonly read and studied, the following is stated by Bartlett: "Though the works of Hippocrates, Galen, Stahl, and others, were not unknown, those of Sydenham, and his followers, were principally studied by our oldest practitioners, till the time of Boerhaave, whose invaluable labours commenced in 1701, which, with the commentaries of Van Swieten; the practical writings of Whytt, Mead, Brooks, and Huxham; the physiology of Haller; the anatomy of Cowper, Kiel, Douglass, Cheselden, Monro, and Winslow; the surgery of Heister, Sharp, Le Dran, and Pott; the midwifery of Smellie and Hunter; and the Materia Medica of Lewis, were in general use at our political separation from the British empire."*

* A Dissertation on the progress of Medical Science in the Commonwealth of Massachusetts. By Josiah Bartlett. Communications of the Med. Soc'y of Massachusetts, vol. 3, p. 240.

Such is a sketch of the state of medicine during our colonial existence. The Revolutionary war succeeded. During that eventful period, our profession stood firm in their country's cause; and the names of Warren,* Mercer,† and Rush,‡ show that they were not idle spectators of the fray. Nothing was done, however, for the advancement of medical science. The newly-formed medical colleges were broken up, and all the energies of the country directed to the attainment of a nation's highest hope and ambition. The revolution accomplished, and an independent government established, a new career was commenced. In common with every thing else, medicine felt the sacred impulse, and during the brief period of our independence, how has the scene changed! Instead of the feeble beginnings of one or two institutions, about thirty medical colleges are now to be found in different parts of our country; every city has its hospitals; a thriving professional literature has sprung up among us, and we can now boast of authors whom we are not ashamed to mention along with those of European birth. What nation ever accomplished so much in an equal space of time, and under equal circumstances?

J. B. Beck.]

Dissertation on the State of Medical Science, from the Termination of the Eighteenth Century to the Present Time.

CHAPTER I.—*Introductory observations—Importance of Comparative Anatomy and Physiology, as extending the foundations of medical science—Misapprehensions involved in the general principles of Hoffmann and Cullen—Improvements recently effected in the physiology of the essential conditions of life in the higher animals—in the physiology of the Nervous System—in other departments of physiology—Vital changes in the fluids, as well as in the solids, must be held to be ultimate facts in physiology and pathology.*

In attempting to give a general view of the most important changes of doctrine and improvements of medical science which have been made since the close of the last century, as well as of the leading facts which have engaged the attention of the profession during that time, we do not hesitate to acknowledge our strong sense of the extent and difficulty of the undertaking, but trust that our remarks will be received with candour and impartiality.

The First Lines of Dr. Cullen and the Treatise on the Blood, &c. by Mr. Hunter, may be held to be the most important systematic works on medical subjects which were published, in Britain, during the latter part of the eighteenth century; and all the additions to medical knowledge, and improvements in the principles of medicine, which have been made since they were published, may be included in such a review of the recent progress of the science.

When we compare the general notions as to medical science which are prevalent at the present day, with those which are recapitulated by Dr. Cullen in the Introduction to the last edition of his First Lines, as holding their place, up to his time, in the schools of medicine, the most important observation that occurs to the mind is the present general, although not always avowed recognition of this principle:—That the phenomena of disease, like all other phenomena of living bodies, belong to a class of facts, and constitute a subject of investigation, altogether distinct from those which are presented by any forms or changes of inanimate matter. Dr. Cullen states that "the Mechanical Philosophy had been applied (soon after the discovery of the circulation) towards explaining the phenomena of the animal economy, and continued till very lately to be the fashionable mode of reasoning on the subject;" and he very properly admits that it must "still in some respects continue to be applied," but adds that "it would be easy to show that it neither could, nor ever can be, applied to any great extent in explaining the animal economy." Now an important step has been already made in the progress of medical science, when this proposition has received the general assent of the profession,—and when the study of Mechanical Philosophy is recommended to the student of medicine, not as one of the foundations of medical science, (with the exception of a few simple applications of its principles in some parts of Physiology,) but simply as an example of successful scientific investigation.

A nearly similar observation may be extended to the study of Chemistry; for although it be true that all vital actions are attended by, and in part dependent on, a series of continual chemical changes, and although a certain knowledge of chemical principles is therefore required of the physiologist, yet the chemical changes of animated nature are as distinct from those which we produce at pleasure in dead matter, as the stimulation by nerves and the contraction of muscles are distinct from any of the principles and powers of mechanics. Excepting in its application to the Materia Medica, the chemistry of dead matter avails little in the science of Medicine; and although little progress has yet been made in the inquiry, it has become obvious that the chemistry of living matter is, in fact, one of the departments of Physiology, the peculiar laws of which must be studied and ascertained in living bodies themselves, and in the products of their vital changes. The chemical part of the changes that take place in respiration, and in the digestion and assimilation of food, has been carefully and successfully investigated of late years; but the result is, that merely chemical principles are equally inadequate for the explanation of those changes, and of their effects on the system, as merely mechanical principles are for the explanation of the movements

* Major General Joseph Warren was born at Roxbury, near Boston, in 1741. He studied medicine and practised his profession at Boston. At the first breaking out of the Revolution, he turned his attention to arms, and was slain at the battle of Bunker Hill, June 17, 1775. See Thatcher's Medical Biography.

† "Hugh Mercer, M. D., a general in the Revolutionary war, was a distinguished physician, who, like Warren, fell in the defence of the liberties of his country. He was a native of Scotland, and educated at Edinburgh. He early emigrated to Virginia, and settled at Fredericksburg, where he practised medicine for several years with great reputation. During the Revolution, he zealously engaged in defence of the liberties of his adopted country, and fell in the battle of Princeton, 1777." Prof. Sewall's Lectures, 1825, p. 60.

‡ Dr. Rush was a member of the Congress of 1776, and one of the signers of the Declaration of Independence.

which, in the economy of the higher animals, are equally essential parts of these functions.

It is farther obvious, that all those functions of living bodies which are now properly distinguished as the *animal* functions, i. e. all those which necessarily imply the intervention of some mental act, can derive no elucidation from anything that is ever seen in the inanimate world; and that, in so far as the science of medicine is dependent on the knowledge of them, it must be built on observations made on the living state of animals exclusively.

Although, therefore, some degree of acquaintance with other natural sciences is properly expected of a physician, yet it is chiefly as an exercise of the understanding that the study of these sciences must be recommended. The direct applications of any parts of the knowledge derived from that study, either in the science or practice of medicine, are very partial; and the cultivation of that knowledge is chiefly desirable, "not for the sake of the fruits, but to be ploughed in as a dressing to the soil."

It remains, therefore, as the only rational foundation of medical science, that we must trust to the careful examination of the structure and functions of living bodies themselves, as existing in health, as altered by injury or disease, and as influenced by remedies. It is by accurate observation and careful generalization of facts confined to this department of nature itself, that the general principles or Laws of Vitality (whether in the state of health or disease) are ultimately to be made out, which will bear the same relation to the science of medicine, as the principles of gravitation, of the inertia of matter, of motion communicated by impulse, &c. bear to mechanical philosophy; or as the laws of heat, of electricity, and of chemical affinity bear to chemistry.

But in order that this may be effectually done, it is now generally admitted that an extension must be given to the inquiry which has not until lately been in the contemplation of most medical inquirers. It is only by tracing the varieties of organization and of vital phenomena throughout the different order of animals, and even in vegetables, that we can expect to be able to ascertain the most general laws of vitality, and distinguish them from the conditions of existence of individual families or genera: it were easy to show that limited and erroneous ideas have originated from the attention of medical inquirers being fixed on the economy either of the human body or of those animals only, which approach the nearest to man; and that the true foundation of medical science must be laid in an extensive knowledge of anatomy and physiology, *human and comparative*. The clear perception of this truth has been gradually impressed on the medical inquirers of the present age, chiefly by the influence of the labours of John Hunter in this country, of Blumenbach in Germany, and of Cuvier in France; and the great, though hitherto unfinished work of Tidemann may be quoted as evidence of the form and extent which have thus been given to medical science. It must, however, be admitted, that in the writings of professed comparative anatomists much talent and ingenuity have been fruitlessly exerted in questions as to the analogies of structure to be traced in the different classes of animals, which have no bearing on strictly physiological or medical inquiries.

In the systematic writings of Hoffmann and Cullen, "the state and affections of the *primary moving powers* of the animal economy," as distinguished from any principles of chemistry or mechanics, were first regarded as the main objects of inquiry in the investigation of diseases; and the proper path of pathological inquiry may be said, therefore, to have been opened by these authors. But it will now be pretty generally admitted, that these moving powers of the animal economy, so long neglected in the older schools of medicine, were erroneously conceived by them. Hoffmann, in a passage which is quoted by Cullen, as giving the best epitome of his doctrines, asserts, "quod solus *Spasmus*, et simplex *Atonia*, æquabilem, libreum, ac proportionatum sanguinis omnisque generis fluidorum motum, quibus excretionum successus et integritas functionum animi et corporis proximè sistitur, turbando et prevertendo, universam vitalem œconomiam subruant et destruant; atque hinc universa Pathologia longe rectius atque facilius *ex vitio motuum microscosmicorum in solidis*, quam ex variis affectionibus vitiosorum humorum, deduci atque explicari possit; adeoque omnis generis ægritudines internæ ad *præternaturales generis nervosi affectiones* sint referendæ." Now this passage plainly implies two propositions, which were maintained by Cullen as well as by Hoffmann, and formed an essential part of the system of both, but which subsequent inquiries have shown to be not only hypothetical, but most probably erroneous,—viz. *first*, that all movements of fluids in the living body depend on the impulse of moving solids; and *secondly*, that all movements of living solids depend essentially on the nervous system.

In opposition to these ideas of the "moving powers of the animal economy," two propositions may be stated as very prevalent opinions, if not generally admitted principles, at the present day:—

1. That, although the principle of *voluntary motion* certainly resides in the Nervous System, yet the supposition of the principle of *all vital motion*, or as some have expressed it, the principle of life itself, being lodged exclusively in the Nervous System, is an unfounded hypothesis; and, 2. That the fluids of living bodies are liable to movements, or variations of movement, peculiar to their living state, but independent of any impulses which they receive from the solids.

The first of these propositions is the general result of the inquiry as to the relation of muscular motion to the nervous system of animals, which was begun in the last age by Haller and Whytt, and continued in the present chiefly by Bichat, Legallois, and Flourens in France, and by Cruickshanks, Brodie, and Wilson Philip, in this country. It has been clearly shown, indeed, that the involuntary motions of the body, and the property of Irritability itself, resident in the muscular fibres, are *liable to much alteration* from causes acting in the Nervous System; but there is not only good evidence against the hypothesis of their *dependence on an influence or energy constantly flowing into the muscles through the nerves*, but no satisfactory evidence that any intervention of

change in a nerve is necessary, to enable a stimulus to act on a muscle.

The second proposition, stated above, is the general result of many observations made on different classes of living beings, and particularly on the movements in the capillary vessels of vertebrated animals, by Haller and by various physiologists and pathologists, chiefly in Germany, since his time. These observations have, perhaps, hitherto attracted less attention in this country than they deserved; but many facts might be stated to show, that no powers of contraction which can be either attributed to the smaller vessels of animals from what is known of the larger, or detected by microscopical examination of the small vessels themselves, will suffice to explain those fundamental changes, as to the distribution of the blood through the capillary vessels of the body, which led both Hoffmann and Cullen to look to a disordered action of these vessels as the true origin of the most important diseases.

It is easy to perceive that these alterations in the views of physiologists as to the "primary moving powers of the animal economy," must necessarily involve a most material change in any speculations which we can entertain as to the fundamental nature of diseased actions.

It may be added that another principle, which held an important place in Pathology even in the writings of Cullen, and likewise, in a somewhat different form, in those of Hunter, has since been very generally and properly abandoned. This is the principle of the Autocrateia, or Vis Naturæ Medicatrix, not indeed regarded by Cullen as it had been by Stahl, as an attribute of the human mind, but still held out as a power of the animal system, to which changes occurring in the course of disease might be reasonably referred, and by which they might be explained.

It is perfectly true that the greater number of diseased actions are essentially temporary in their nature, and that there are various and wonderful provisions of nature for avoiding and repairing injuries, to which the body is liable; but unless we substitute *final* for *physical* causes,—the "id propter quod" for the "id ex quo,"—the knowledge of this general fact gives no assistance in tracing the laws of the animal economy, to which either these or other changes, occurring in disease, are to be ascribed. The critical termination or gradual decline of idiopathic fever, the resolution of inflammation, the exudation and organization of lymph on inflamed surfaces, the processes of suppuration and of sloughing, the function of healthy absorption, and the increase of absorption from pressure, are all examples of changes which frequently, although not uniformly, tend to the preservation of life; but it is quite certain that these different processes depend on very different principles or laws of the animal economy; and the knowledge of the fact, that these different laws are wisely designed for the preservation of life, gives no assistance in the inquiry as to the nature of the laws themselves, which is the inquiry that the pathologist has to pursue.

It must be owned, however, that although, in these different aspects, we may hope that medicine is cultivated at present on sounder principles than fifty years ago, yet as there has been no strictly systematic writer of high repute since the time of Cullen, so the attention of medical men has been seldom fixed on these first principles of the science; and their efforts have been directed chiefly to the elucidation of subordinate departments, capable of more direct practical application, and demanding a more detailed notice.

I. The first of the more special improvements which may be noticed as having been effected within the last forty years is, the elucidation of those fundamental questions in Physiology which bear most directly on Pathology, viz. those which illustrate the causes of *sudden or violent death*; and the more precise information which we now possess on these points may be traced, in a great measure, to the labours of Bichat, who fixed the attention of physiologists on the essential distinction of the Organic and the animal life of all the more perfect animals, and on the importance of the function of Respiration, as the closest and most permanent bond of union between the two. This intermediate character may likewise be assigned to digestion, and to all the functions necessary to the life of animals which are dependent on movements excited, directly or indirectly, by *sensation*, as distinguished from those strictly organic functions in which no mental act is concerned.

The ideas of Bichat of the three modes of sudden death, that beginning at the brain, at the lungs, and at the heart, were in some respects incomplete. He was not aware that by certain kinds of injury of the brain or spinal cord, death may be produced, not through the intervention of failure of respiration, (as in the case of what is strictly called death by Coma,) but by a sedative impression suddenly communicated to the heart, and therefore strictly in the way of Syncope; he did not seize the right view of the manner in which the circulation is brought to a stand when the access of air to the lungs is in any way obstructed, and was so far inaccurate in his notion of death by Asphyxia; he had not studied, at the time of his death, the action of Poisons on the animal economy, so as to be aware of the illustrations of his own principles which these afford; and he had made little application of his views as to violent death to the more complex changes which constitute disease. But these deficiencies have been since supplied. The experiments of Legallois and of Dr. Wilson Philip, and the clinical observations of Brodie, Travers, and others, have sufficiently illustrated the direct effect of violent concussion, or shock, in whatever manner produced, on the heart and other organs of circulation. The dependence of the death by asphyxia, not on the loss of power in the heart, but on the stagnation of blood in the lungs, and failure in the supply of blood to the left side of the heart, has been satisfactorily established by the experiments of Dr. Williams of Liverpool, and Dr. Kay of Manchester. The different modes in which death is produced by Poisons (which are the more important as they are the facts in nature most analogous to the changes which constitute the most deadly diseases) have been clearly pointed out by Sir B. Brodie, and amply illustrated by the researches of Orfila and Dr. Christison. What is more important in a pathological view is the peculiar depressing influence on the vital actions of

the sanguiferous system, which many poisons, belonging to different classes, (e. g. opium and arsenic,) are shown to exert;—which in the case of some of the mineral and vegetable poisons, as arsenic or tartar-emetic in large doses, tobacco, digitalis, hydrocyanic acid, is the immediate cause of death;—and which is the most striking part of the effect produced by animal poisons, such as that of a venomous serpent or the most virulent contagious effluvia. It may be added that the different modes in which excessive Cold and excessive Heat, and Electricity or lightning, produce death, have been sufficiently elucidated by experiments of Chossat, Brodie, and others, and by cases recorded by many practical observers; and that the different effects of violent Hemorrhages have been carefully investigated by Dr. Marshall Hall, Dr. Blundell, and others.

From all these observations it is now fully understood that the ultimate effect of all causes of sudden death may always be referred to their arresting, in ways which we can distinctly specify, the flow of arterial blood throughout the body; which is, in all cases, the essential condition of all its vital actions, although in different tribes of animals, and in different states of the same, the degree of rapidity of the requisite supply of this blood is remarkably various.

It is also distinctly understood that, in all cases of sudden death in the higher animals, most nearly approaching to man, this essential condition fails from one or other of two general causes, either because the vital agency of the powers moving the blood is directly depressed or suspended, or because the action of the air on the blood is obstructed, and the blood therefore stagnates in the lungs;—that the vital action of the sanguiferous system may be suspended in two ways, either by various agents, chiefly acting through the nervous system, which impress it in the manner of a Concussion or Shock, or after the manner of one of the virulent poisons abovementioned, which act nearly as a concussion does; or by abstraction, sudden or gradual, of the vital stimulus;—and lastly, that the action of the air on the blood may be obstructed also in two ways, either by such injury of the Nervous System as produces insensibility or Coma, and ultimately arrests the mechanical actions of respiration, which depend on sensation; or by direct impediment to the admission of air to the Lungs, arresting the respiration more directly or producing Asphyxia.

Although it is only in a few cases of disease that life is extinguished in so simple a manner as in any of these instances of violent death, yet it is plain that the scientific treatment of all diseases must be very much guided by a clear perception of the landmarks which are presented to the careful observer, by the study of these simplest cases in pathology.

II. The next important addition to the science of medicine has been furnished by the labours of those physiologists who have done so much within the last twenty years to determine the different purposes which are served by the different parts of the Nervous system. The general result of these inquiries may be thus stated: that the very different offices to which the nervous system has long been known to minister, in different parts of the body, are not determined, as was formerly suspected, by the various organization of the parts, but by the various endowments of different portions of the nervous matter itself, in relation to those mental acts of which they are the seat and the instrument.

The dissections, experiments, and clinical observations of Sir Charles Bell, Mr. Shaw, and Mr. Mayo, in this country, of Magendie, Serres, Desmoulins, and Flourens in France, and of Rolando and Bellingeri in Italy, [and of Valentin, J. Müller, and others, in Germany,] are the most important of those by which it has been ascertained, that the conditions which are necessary to all the sensations, and to the excitement of all muscular motions by mental acts, are confined to those nerves, and to those portions of the spinal cord, and its immediate prolongations within the cranium, to which we now give, without difficulty, the names of sensitive and motor respectively. We can specify those portions of this Cerebro-Spinal Axis, on which each of the sensations peculiarly depends; we can point out the use of parts within the cranium, in immediate connection with the Cerebro-Spinal Axis, by which voluntary or instinctive motion in different directions is determined; we can form some idea of the parts of the nervous system, and of the peculiarities of structure, by which the influence of mental acts over the involuntary motions and other organic functions, is maintained; and we can show that the brain and cerebellum are not essential to the performance of the functions of the spinal cord and nerves; that they are neither required for sensation, nor for those instinctive actions which are most intimately linked with sensations, but are superimposed on those organs with the intention of combining sensation and instinctive action with the higher attributes of mind. These parts of the nervous system furnish the conditions, not of sense or motion, but of intellect, of desires, and moral feelings; they are required, not in order that sensations may be felt, but that they may be remembered and availed of for that purpose,—not in order that volitions may act as stimuli on muscles, but that they may be so excited, and so succeed one another, as to produce regular and useful voluntary actions, under the guidance of desires, and of judgment and experience, as distinguished from blind instinct.

[The views of Dr. Marshall Hall, in regard to the true spinal system of nerves, have shed great light on many circumstances connected with the nervous system, which were previously regarded as anomalous. Dr. Hall divides all the nerves into 1. the *cerebral*, or the sentient and voluntary; 2. the *true spinal* or excito-motory; and 3. the *ganglionic*, or the nutrient and secretory. He believes, that a peculiar set of nerves constitute, with the true spinal marrow, or the gray matter as their axis, the second division; the *excitor* nerves pursuing their course principally from internal surfaces, characterized by peculiar excitabilities, to the true medulla oblongata and medulla spinalis; and the *motor* nerves pursuing a reflex course from the medulla to the muscles, having peculiar actions concerned in ingestion and egestion. The views of Dr. Hall on the excito-motory function have been embraced by J. Mül-

ler, Grainger, Carpenter and most observers, and have been extensively applied to the elucidation of spasmodic diseases more especially; some of which are induced by causes seated in the spinal marrow, or at the centre, whilst others are caused by excentric irritation, or in a reflex manner.]

So far the different endowments of the different parts of the nervous system may be held to have been determined by observation and experiment; and if we decline to enter farther into the speculations of phrenologists (which have attracted so much attention of late years), as to the connection of the individual parts of the brain with the different intellectual powers, or with the exercise of these powers on particular objects of thought, it is not because we regard the general principle of those speculations as unphilosophical, but simply because they are founded on a kind of observations which is open to various sources of fallacy, and derive little or no support either from experiments on animals or pathological observations on the human body, and appear, therefore, to be built on insufficient evidence.

The knowledge of the endowments of the different parts of the nervous system, so far as it has been hitherto attained, is a great and important step in physiology; it is of importance in the diagnosis of many of the diseases in which the nervous system is concerned, as fixing the precise seat of these diseases; and it enables us to explain the great diversity of symptoms, which may result, in different cases, from apparently similar lesions of the brain and cerebellum, and so to surmount what was formerly a serious difficulty in pathology;* but it is susceptible only of occasional and partial application in the practice of medicine, simply on this account,—that practical questions as to the treatment of diseases, especially of different diseases of the same texture, must always turn much more on their nature than on their seat.

III. Many other improvements in Physiology have been effected since the close of the last century, on which it were out of place to dwell here, because they are hitherto susceptible of still more partial application either in pathology or practice; but which must not be omitted in any general account of the progress of medical science. The chemical analysis of the Blood has been carried to a high point of perfection; and the varieties in the proportion of its constituents in different circumstances, the essential differences of venous and arterial blood, the essential nature of the process of coagulation, and the circumstances by which it may be accelerated, retarded, or prevented; the alterations effected by inflammation in the proportion of the fibrine, and in the property of coagulation; the organization of the fibrine which exudes from inflamed surfaces; and the proofs resulting from these last facts, of the existence of strictly vital properties in the blood as well as in the solids of the body, are all points that have been elucidated by numerous experimental inquirers, following the path which had been opened by Hunter and Hewson; and among these Bostock, Berzelius, Marcet, Hey, Thackrah, Davy, Prévost and Dumas, Le Canu, Denis, Gendrin, Schroeder Van der Kolk, Babington, and Prater, [Andral and Gavarret, Mandl, Donné, Wagner, Gulliver, and Wharton Jones,] may be particularly mentioned.

The nature of muscular contraction in general has been more fully investigated by Prevost and Dumas than by any previous physiologists; and the question, repeatedly agitated, whether there be any change of volume in the fibres at the time of their contraction, has been resolved in the negative by these authors, by Mayo, and others. [The whole subject of the histology and physiology of the muscles, has been ably investigated by Bowman, Gerber, Skey, Martin Barry, Bishop, and others.] The vital actions of the heart have been particularly studied, and the use of its valves, and of the peculiar convoluted structure of its muscular fibres, if not fully ascertained, have been much elucidated by the dissections and experiments of Gerdy, of the late Dr. Duncan, of Williams of Liverpool, Corrigan, Hope, Carlile, [Pennock and Moore, Cruveilhier, Williams of London,] &c., as well as by the clinical observations of Laennec, and the correction of some of his conclusions by Professor Turner and others. The nature of the vital power which can be ascertained to exist in arteries has been satisfactorily determined by the experiments of Parry, of Wedemeyer, and of Poiseuille. The auxiliary forces which contribute to the flow of blood along the veins, and particularly the effect produced on its movement there by acts of inspiration and expiration, have been partially indicated by Carson, and more clearly pointed out by Magendie and Sir D. Barry. And the flow of blood in the capillary vessels, under various circumstances, has been carefully examined, and subjected to comparison with the movement of fluids in the lower classes of animals and in vegetables, by numerous observers, of whom the most deserving of notice are Thomson, Hastings, Black, and Marshall Hall in this country; DuTrochet, [Magendie,] Leuret, and Gendrin in France; and Schultze, Döllinger, [Wagner, J. Müller,] and Kaltenbrunner, in Germany.

On the whole, it may be stated that the investigation of the powers by which columns of blood are moved through the larger vessels of the human body, seems to be nearly complete; but farther inquiries are still demanded, to determine the nature and estimate the efficacy of the powers, by which the movement of the blood is affected and its distribution regulated, after it has been diffused throughout the innumerable ramifications of the capillaries; and this deficiency is the more important, as it is clearly in the alteration of vital actions of which the capillaries are the seat, that all the most formidable diseases originate. The prin-

* It is due to the memory of the late Dr. Gordon of Edinburgh, to state, that as early as 1813 he had inferred, from pathological facts already known, that the brain and cerebellum are not concerned in sensation nor in certain voluntary actions. He thought that palsy, in any of its forms, when produced by disease within the cranium, higher than the medulla oblongata, might be referable, not to loss of the essential conditions of sense or of voluntary power, but to what he called a "noxious influence," transmitted in some such cases, and not in others, from the seat of the disease to the nerves of the parts affected. Of the share which the medulla oblongata and spinal cord may have in these functions he spoke doubtfully, as the state of our information at that time required. The facts which he had collected on this subject are contained in a paper in the twenty-fourth volume of the Edinburgh Review.

ciple of *Endosmose* and *Exosmose*, illustrated by the experiments of Dutrochet and others, certainly does not develop the sole agent of vital movement in the capillaries; but it exhibits movements, even in inanimate fluids, which may be said to bear the same relation to the chemical actions of these fluids on one another, as certain of the movements of living fluids bear to the vital changes to which they are destined.

In regard to the functions of Nutrition, Secretion, and Excretion, to which the circulation is subservient, perhaps the most important information, lately obtained, is of a negative character. Notwithstanding the opposite opinion of some eminent physiologists, it may be stated as the general belief, and as a fair inference from a review of the different departments of living beings, as well as from experiments and observations on the higher animals, that these processes are independent of any influence or energy necessarily derived from the nervous system.*

It may also be laid down as a principle established, chiefly by the observations of Cuvier, that the differences among the products formed from the blood in the living body, great and numerous as they are, cannot be explained by the differences of organization, or by any peculiarities of the vascular arrangements, of the parts where they show themselves.

Several circumstances, in regard to the intimate structure of organized substances, both animal and vegetable, have lately attracted much and deserved attention, as clearly distinguishing them from any products of the chemical attractions which subsist among the particles of dead matter. The most important are, the very general tendency of substances which are the result of vital action, to take the form of globules, or rather of *cells*, in which a containing cyst and a contained matter are usually discernible; the total absence of crystalline arrangement in the living and growing parts of these textures; and the fact, that the particles of earthy and saline matters which enter into the composition of organized substances, however small their proportion to the whole, are never aggregated together, but are equally diffused through the whole mass, and retain the original form and dimensions, even after the whole of the strictly animal or vegetable matter has been burnt out. These facts, established by Dr. Prout in this country, and by Milne Edwards, Tiedemann, Raspail, and others abroad, clearly indicate that the attractions and repulsions which subsist among the elements constituting organized bodies, at the period of their formation by living action, are essentially different from those by which the same elements are actuated in other circumstances; and establish the existence of a distinct set of laws, regulating their combinations in living structures, to which the general title of *Vital Affinities* has been happily applied. [A comprehensive description of the opinions of many recent histologists on *cells* and *cell-life* is given by Dr. Carpenter in the *Brit. and Foreign Med. Review* for Jan. 1843, p. 249.]

As the analysis of the blood has been improved, so many of the proximate principles which go to the composition of animal substances have been detected in it, or procured from it by very simple means, that the processes by which the solids of the living body are nourished, or the prepared fluids furnished, have been gradually more and more regarded as nearly approaching to simple transudation, or, as it has been appropriately termed, Chemical Filtration. And since the process of assimilation or sanguification, by which foreign matters are added to the blood either in the adult or fœtal state, has been minutely traced, so much contrivance for the gradual formation of the blood has been developed, that we are the less surprised to find so many proofs of its very heterogeneous nature when it comes to the extremities of the arteries, and is applied to the purposes of nutrition and secretion; and of the apparent simplicity of these processes themselves.

One principle, at least, may be held to be nearly established on this subject, that the materials of the different *Excretions* already exist in the compound blood, and are only evolved or separated, not formed from the blood, at those organs at which they respectively appear. This is certain as to the urine, from the result of the experiments of Prevost and Dumas, and of pathological observations by Dr. Christison and Dr. Bostock in the human body, from which it appears that when the kidneys are extirpated or more gradually obstructed, and rendered unfit for their office, the urea, or peculiar matter of the urine, shows itself in the blood. As the peculiar matter of bile appears now to have been detected, even in healthy blood, and as there are undoubtedly cases of intense jaundice, in which the bile-ducts appear on dissection pervious and *empty*, even throughout the substance of the liver,—where there is therefore no reason to suppose that any secretion of bile had taken place,—we have good grounds for extending the same conclusion to the liver, as we have stated in regard to the kidneys. And there is still less difficulty in extending it to the excretions by the skin and the lungs. We may consider the function of excretion, therefore, (which is a concomitant of vital action in all living beings without exception,) as having its origin in all parts of vital action in all living bodies, or more probably *in the nourishing fluid* which penetrates and vivifies them all; and as the necessary complement of the process of assimilation, by which extraneous substances are incorporated with organized matter.

The important discoveries as to the nature of the corresponding process of Absorption, which have been made of late years by Magendie, Ségalas, Fodéré, Meyer, Tiedemann, [Sir D.] Barry, and many others, (when duly compared with the comments of other physiologists,) may be thus expressed,—That although the set of vessels described for a century past by the name of absorb-

* It is perfectly in conformity with this doctrine to state, that the nutrition of certain parts, as of voluntary muscles and the organs of sense, and that the secretions of other parts, especially of mucous membranes, are *habitually excited* by voluntary motions and by sensations, and therefore become deficient when certain nerves of voluntary motion or of sensation, are injured or palsied. This principle seems to furnish the true key to the facts observed in numerous recent experiments on animals, by Brodie, Wilson Philip, Swan, Breschet, Leuret and Lassaigne, Magendie, and others, as to perversion of secretion and nutrition from section, particularly of the fifth and eighth nerves. And the same principle may be applied to various important phenomena in disease.

ents are really destined to the office of absorption, and their structure, in various ways, is peculiarly adapted to it, yet it is not through them, nor through any one set of vessels exclusively, that the absorption of extra-vascular substances into the circulating mass is effected; that a function precisely similar is executed in many living beings, without any set of vessels being appropriated to it; and that the absorption of extra-vascular matters in the higher animals must be ascribed, therefore, in the last result, to peculiar relations subsisting, in the living state, between those matters and the circulating blood, rather than to the peculiar nature or forms of the vessels which are the organs of absorption; and, accordingly, that the degree of absorption is very much influenced by two circumstances in the condition of the circulation at the part where any such extraneous matters may lie,—viz. by the fulness of the vessels, and by the rapidity of the current at that part; being always diminished when the vessels are much distended, and likewise when the flow along these vessels is much retarded or suspended, as by the removal of atmospheric pressure from any portion of the surface of the body.

Another principle in regard to absorption in the more perfect animals, of complex structure, which recent inquiries have illustrated, and which has been already briefly noticed, as probably of fundamental importance, viz. the careful provision which nature has made for the very *gradual intermixture* of any foreign matter, thus introduced, with the nourishing fluid of the body receiving it. Thus, when extraneous matter is received into the primæ viæ, it is not only acted on by the fluids there provided for its reception, and part of it rejected, but the absorption of what is capable of assimilation is divided between two sets of vessels; what is taken up by the veins is carried to the liver, and certain combinations of the elements contained in it are there expelled;—what is taken up by the lacteals is mixed with certain elements of the blood in the absorbent vessels, and particularly in the mesenteric glands; and both portions are carried through the capillaries of the lungs,—where certain matters are evolved from them, and at least one important element added to them,—and are subjected to thorough agitation and intermixture on both sides of the heart, before they are admitted into the arteries, in a condition fit for the purpose of nutrition.

That these arrangements, and others which have a similar effect in the lower animals, are intended to secure the very gradual intermixture and incorporation of fresh nourishment with the blood, we shall be prepared to admit when we remember, that throughout all the classes of organized beings, and in all periods of their independent existence, the assimilation of the crude nourishment, taken in from the external world, is always effected by means of organized matter already existing in each living structure itself; and farther, that in the case of animals at least, the greater part of the ingesta, which are subservient to nutrition, are themselves organized substances, the products of vital action in some of the lower orders of living beings, and the assimilation of which may therefore be said to have commenced in these lower orders of the animated creation. From such facts, it is obvious that there must be contrivances, in all living beings, for the fulfilment of those still mysterious laws and conditions, by which the chemical changes effected by them on the surrounding elements are regulated and controlled; and among these contrivances, the arrangements of the different absorbent vessels and of the excreting organs must evidently be ranked.

The chemical nature of the changes which take place in the air, and in the blood, or nourishing fluid of all living structures, in respiration, has been often and carefully investigated since the time of Black, Priestley, and Lavoisier, especially by Ellis, by Allen, and Pepys, and more lately by Edwards, Dulong, [Gmelin, Tiedemann, Mitscherlich, Liebig,] and Collard de Martigny. The general result is, that the absorption of oxygen and the evolution of water and carbonic acid are the essential changes; but that the products thus evolved are the result, not of a simply chemical action at the lungs or corresponding organs themselves, but of the vital actions throughout the system, by which the blood acquires the venous character before it reaches the lungs. The adaptation of arterial blood to the maintenance of vital action in general, and of circulation in particular, seems to be one of the primary laws or conditions of vitality, for which it is in vain to look for an explanation, and the mode of operation of which is illustrated by what has been already said of the nature of death by asphyxia.

The questions, whether the maintenance of the heat of living animals is satisfactorily explained by the strictly chemical changes that take place in the body, and especially at the lungs, and how far it is dependent on any action of nerves, have been prosecuted with great zeal, since the time of Black, Crawford, and Lavoisier, by Sir B. Brodie, Dr. Davy, Legallois, Hales, Drs. Wilson Philip and Hastings, Chossat, Edwards, Dulong, and Despretz, [Liebig,] and others. The general conclusion is in favour of the sufficiency of the chemical changes to explain it, and of the influence of that particular change on which the evolution of carbonic acid depends, in elevating the temperature of animals; and there is, perhaps, no case in physiology to which the maxim, "Frustra fit per plura quod potest fieri per pauciora," is more fairly applicable: but two points have been likewise ascertained, which were not in the view of the first speculators on this subject, viz. 1. That the chemical changes on which the temperature of the living body depends, cannot be confined to the lungs, nor to the formation of carbonic acid in the body; and, 2. That these changes are remarkably liable to influence from causes, and especially from injuries, affecting the nervous system.

The power which living animals possess of maintaining a temperature lower than that of the surrounding air, has been shown by De la Roche and Berger, and by Edwards, to depend merely on the increased evaporation from them, and therefore on a simply chemical principle.

In regard to the function of digestion, the most important additions to our knowledge have been made by Drs. Marcet, Prout, Wilson Philip, and Sir B. Brodie, in this country, by Tiedemann and Gmelin, in Germany, and by Magendie, Londe,

and Leuret and Lassaigne, in France; and of these the following chiefly demand attention:— 1. The division of alimentary matters into the great families of albuminous, saccharine, and oily; and the necessity of mixture of at least two of them for the nourishment of man and of the most analogous animals, — (another fact which shows how much hitherto unexplained contrivances must be included under the term assimilation of food.) 2. The secretion of an acid solvent liquor, containing the muriatic acid, in the stomach, subsequent to the reception of aliment, and regulated to a certain degree in its quantity and strength by the nature of the aliment received. 3. The great diminution of this secretion, usually caused by section of the par vagum, particularly in the neck, in circumstances when we know that the sensations of the stomach and of the lungs are very much perverted. 4. The appearance of matter possessing in some degree the characters of albumen, in the chyme thus formed, even in the stomach, and the increasing proportion of this matter in the upper part of the bowels, and in the contents of the lacteals and thoracic duct. 5. The formation of globules, similar to those of the blood, in this albuminous matter, likewise commencing in the stomach. 6. The gradual combination of the acid and oil of the chyme with the alkali of the bile, in the course of the small intestines, and the gradually increasing proportion of the peculiar animal and excretory matter of the bile, in tracing the contents of the intestines downwards, as the acid and the albuminous matters disappear. 7. The albuminous and slightly acid nature of the pancreatic juice, its greater abundance in herbivorous animals, and the corresponding fact, that in the human body vegetable food is chiefly acted on after it has passed the pylorus. 8. The reappearance of acidity at the cœcum, and probably renewal of a certain degree of the digestive process in the great intestines.

[The observations of Dr. Beaumont, of the United States Army, on an individual having a fistulous opening into the stomach, have confirmed many of these positions; and thrown great light on the phenomena of digestion. It would seem, from the experiments of Eberle and Schwann, that a nitrogenized substance is thrown off from the stomach, which the former terms *pepsin*, and which is an active agent in digestion. The agency of this pepsin is regarded by Liebig to be similar to that of *diastase*, in the germination of seeds. Both are bodies in a state of transformation or decomposition; — the latter effecting the solution of the starch—that is, its conversion into sugar; and the former, the conversion of alimentary matter into chyme. The prevalent belief amongst physiologists and chemists is, that pepsin, by inducing a new arrangement of the elementary particles or atoms of the alimentary matter, disposes it to dissolve in the gastric acids. Liebig does not believe that the digestive process is a simple solution, but a species of fermentation, not identical, however, with any of the known processes of fermentation occurring in organic matters out of the body.]

Besides the great discovery of the various endowments of different parts of the nervous system, some farther improvements have been effected in that part of physiology which treats of the strictly animal functions—sensation, thought, and voluntary motion. Various facts as to the conditions requisite for the exercise of the senses, and particularly of the sense of sight, have been ascertained; and the general views of physiologists as to the information which the senses convey, and the mental processes which they excite, have become, at least in this country, more scientific and precise.

Perhaps the most important proposition which can be stated in this part of the subject, is one which has been best illustrated by Dr. Reid and the other Scotch metaphysicians, — that many of the mental acts, which are naturally and uniformly excited by the exercise of the senses, bear no resemblance whatever to the sensations from which they originate; that not only the general ideas which arise in the mind in consequence of impressions from without, (such as time, space, number, power, &c.) are wholly unlike any thing which was ever presented to our senses, but the notions which we form of the qualities of the objects of sense themselves, (such as hardness, softness, extension, motion,&c.) bear no resemblance to the sensations which lead us to form them. Our ideas, therefore, are not, as some philosophers have supposed, merely "transformed sensations;" nor does the external world itself appear to us as the "express image of our sensations;" and the true source of much of our knowledge is, not in the mere intimations of sense, but in the *judgments* which by the constitution of our nature *we intuitively form*, in consequence of receiving these intimations. (See Stewart's Philosophical Essays, "On Mr. Locke's Account of the Origin of our knowledge.")

When this principle of intuition, which must necessarily be admitted as one source of the information acquired through the senses, is duly considered, it will appear that we have no means, *à priori*, of judging what is the kind and extent of information, as to the qualities of external things, which any sense may be capable of communicating, to man or to other animals; and it is still doubtful, whether or not many reported cases of alleged transference of the higher or peculiar senses from one part of the system to another, are referable only to this general principle.

At all events, it is obvious that as we necessarily include under the term mental acts many phenomena which are neither included in sense, nor logically deducible from the intimations of sense, the study of these mental acts, as we feel them in ourselves, and as we judge from their results that they are felt by others, (a study which on many accounts demands the attention of the physician,) must be prosecuted quite separately from that either of the sensations or motions of any living beings; and provided that the attention be fixed on matters of fact, and all useless controversies be avoided, this study may be prosecuted with more advantage in the writings of metaphysicians than of mere physiologists. In this view, the treatises of Dr. Abercrombie, on the Intellectual and Moral Powers, are peculiarly valuable, and perhaps the view there given of our mental constitution may admit, for the sake of the medical student, of still further abridgement.

Lastly, in enumerating the additions which physiology has received since the end of the last century, we must not omit the numerous observations which have been made on the necessary conditions of the function of Generation, and on the mode of life and development of the fœtus. These observations have been made chiefly on different classes of the lower animals; and the varieties of this function in the different classes, and the conclusions to be drawn from the study of these, in fixing the essential conditions of the function, have been admirably stated by Cuvier.

The ovum of some of the mammalia has been detected, first by Bäer, in the Graafian vesicle of the ovary; the nature of the changes, at the ovary, which precede and follow the escape of the ovum, and the fallacies attending the appearance of the corpus luteum, have been elucidated (perhaps not yet completely determined) by Sir Everard Home, Magendie, and others; the existence of animalculæ in the prolific male semen has been confirmed by Magendie, and Prevost and Dumas; the necessity of the actual contact of the male semen with the ovum that descends from the ovary, has been put almost beyond dispute by the experiments of Drs. Haighton and Blundell; while the ascent of the seminal fluid in ordinary circumstances to the ovaria themselves has been disproved, both by their experiments and by the observations of Prevost and Dumas. [Still there appears to be but little doubt that the ovum is fecundated in the ovary.]

The changes produced in the uterus by conception, the nature of the connection between the ovum and uterus, and the manner in which the ovum is nourished both before and after the formation of the placenta, have been subjected to new and careful examination, chiefly by Breschet and Velpeau in France, and Dr. Lee in this country. In reference to the general principles of physiology, the most important proposition that has been stated on this subject is that which appears to be nearly established by this last author,—that there is not only no vascular connection between the mother and the fœtus, but none, or next to none between the uterine vessels and the placenta; and, therefore, that there is no force, acting in the way of *propulsion*, which will explain the application of portions of the maternal blood to the nourishment of the fœtus; while at the same time the experiments of Magendie and others have proved, that any substance which may be circulating in the blood of the mother finds ready access to that of the fœtus, but that there is little or no transference of fluids in the opposite direction.

The numerous and careful observations which have been made on the development of the fœtus in its earlier stages, in different classes of animals, by Pander, Wolff, Rathke, Bäer, Prevost and Dumas, [Bischoff, Henle, Martin Barry, Krause, Wagner, Valentin, Purkinje, T. Wharton Jones,] and other, chiefly German physiologists, have sufficiently established, although in opposition to the opinion of Haller, the general doctrine of the Epigenesis, or growth by the *formation* of parts out of the fluids of the ovum, as opposed to that of the Evolution, or growth by the *extension* of parts; and the gradual development of the different organs and textures, the bones, the vascular system, the nervous system, &c., have been minutely traced by Soemmering, Meckel, Tiedemann, Serres, Allen Thomson, and many others. [See an interesting report on the ovum of man and the mammifera, before and after fecundation, by T. Wharton Jones, in *Brit. and For. Med. Rev.* Oct. 1843, p. 513.] The peculiarities of the blood of the fœtus have also been examined; and the curious discoveries of Sir Astley Cooper and Dr. Lee, of the formation of albuminous matter in the thymus gland, and in the liver, of the fœtus, have distinctly shown that here, as well as in the adult, there are contrivances adapted to the general object of Assimilation, the particular intention of which is still mysterious.

The knowledge of the essential nature of the changes, occurring at birth, by which life, previously maintained by organic functions only, is placed in dependence on the sensations of the new being, and so rendered truly animal and independent of the mother, is necessarily dependent on that correct exposition of the essential conditions of life in the adult, to which we have already adverted. The changes in the state of the circulating system, and of the lungs, consequent on birth, have been examined and accurately described by Chaussier and various other authors, particularly with a view to important questions in medical jurisprudence. And those peculiarities of the vitality of the very young warm-blooded animal, in which it approaches to that of the cold-blooded, especially its power of resisting the privation of the natural stimuli of heat and oxygen, have been particularly remarked by Edwards.

Various facts, of great importance as illustrating both the influence of hereditary constitution and of the habits of parents, and also that of climate, air, exercise, diet, and mode of life, on the growth, the healthy functions, and the diseases of the human body, have been ascertained and recorded by different practical authors; the distinctions of the different races of men now inhabiting the earth have been carefully observed by Blumenbach, Lawrence, Prichard, Desmoulins, Mayo, and others; and the peculiarity of some of these races as to liability to, or exemption from, different kinds of disease have been to a certain degree investigated by various authors, since the time of Rush, in America, and by Drs. Fergusson, Johnson, Marshall, and others, who have had opportunities, in the British service, of making such inquiries in different regions of the globe.

In the present state of Physiology, perhaps the most important inference that can be drawn from this hasty survey of the recent additions to the science is that of the extent which must be given to the idea of Vital Action, beyond what can be included in, or explained by, the Vital Motions of living solids. It is true, indeed, as stated by Cullen, that the "primary moving powers of the animal economy" (by which he understood the vital powers of the moving *solids*) must be more or less concerned in all the changes which take place in the healthy body, and in all the deviations from these which constitute disease; but they are only a part, and frequently not the most fundamental part, of these changes. It is probable that there may be movements in the nervous system, corresponding to all the changes, mental or bodily,

which are connected by nature with its living condition; but they are movements which elude our senses; and we must be content to know the changes that take place in the nervous system itself, only by their effects on the mind on one hand, or on the body on the other. As to the changes in the *fluids* of the body which are essential to the life of the solids, it seems certain that even the motions of the fluids in the capillaries, and still more that the peculiar chemical actions to which they are there subservient, cannot be explained either by the ordinary laws of chemistry, or by any modifications of the impulse communicated to them from the solids; and, therefore, that there must be certain Vital Affinities, and Vital Attractions and Repulsions, in which the fluids as well as solids must participate, and on which all vital phenomena are essentially dependent.

When Mr. Knight stated, as the result of a laborious inquiry in vegetable physiology, that the vital power of generating new wood does not reside either in the outer layer of the alburnum or in the inner layer of the bark, but "*in a fluid which pervades the vessels of both*," he stated a principle which is equally applicable to the whole economy of animals; and under which must necessarily be included the most important of those Laws of Vital Action, which it still remains for physiologists to develop. And as we must take the fluids, and the changes proper to the fluids, into account in all attempts at explanation of physiological phenomena, so we must be prepared to admit a Humoral Pathology as essential to the explanation of all the more important phenomena of disease; but this must be a pathology founded on observed changes, not simply of the mechanical or chemical condition, but of the strictly *vital properties* of the fluids, and especially of the blood.

CHAPTER II.—*Recent additions to our knowledge of the external causes of diseases—Of those which operate generally, and of those which are of local and temporary operation only—Additions to our knowledge of the nature and treatment of acute diseases—Of inflammatory diseases — Of their consequences, and varieties—Of idiopathic fever—Its essential distinctions from inflammation—Its varieties and complications — Of other epidemic diseases — Their different modes of fatal termination, and the adaptation of remedies to them.*

Next to the additions which have been made since the end of the last century to our knowledge of physiology, we may place the numerous important observations by which our information as to the *external causes* of disease has been rendered more extensive and more precise. These observations, and the inferences from them, demand the more attention from physicians, that they necessarily involve a kind of evidence essentially different from that on which we proceed in other medical inquiries. And if we durst hope that the progress of human wisdom and virtue would bear any proportion to that of human knowledge, we might expect that the lessons to be drawn from these inquiries would prove of even greater importance to the future happiness of mankind than any which we can gather from the history or treatment of diseases.

These inquiries have in some instances been prosecuted by individuals in civil life; but the opportunities of making decisive observations on some of the causes of disease which occur in the experience of medical officers of fleets and armies, —who are perfectly informed of the whole circumstances of the organized bodies of men under their observation, and often see these circumstances suddenly altered, or have even the power of altering them at pleasure,—are much superior to those which other practitioners enjoy; and the peculiar value of such observations has never been so well understood as during the last war.

In stating the general result of recent observations on the causes of diseases, it is well to keep in view, *first*, the old and well-known distinction of predisponent and exciting causes, and, *secondly*, the division of the latter class of causes into those which result from the very conditions of our existence, and therefore operate generally among our species, and those which are of local and temporary existence only, and are commonly known by the name of morbid poisons.

In regard to the predisposition to disease, many important facts were well known to the pathologists of the last age; but as to one, and that probably the most important of all the circumstances of predisposition, our information has lately been much extended. This is the great predisposition, given to acute diseases especially, by the previous influence of causes of Debility, which may usually be referred either to deficiency of the natural excitements of the human system, therefore to imperfect nourishment, or defective nourishment from previous diseases, impure air, deficient exercise, long-continued heat, long-continued cold, or permanent mental depression; or else to excessive and exhausting excitement, therefore to fatigue, watching, or intemperance of all kinds.

The great amount of disease and mortality, which may be traced to the operation of these debilitating causes, applied long previously to the commencement of any diseased action, has been illustrated by statistical inquiries into the health and probability of life of different classes of the community, and of the inhabitants of towns as compared with those of country districts; and among the authors of such inquiries, Drs. Perceval (of Manchester), Bisset Hawkins, [Sir James] Clark, and M. Villermé, [Quetelet, and Chadwick, and W. Farr,] deserve particular notice. The influence of some of the individual causes now mentioned has been more specifically demonstrated by the experience of military and naval medical officers; among whom we may particularly mention Sir Gilbert Blane, Sir James Macgrigor, Dr. Trotter, Dr. Johnson, Dr. Robertson, and Dr. Lus-combe.

Of those exciting causes of disease which are of pretty uniform operation, the application of cold is that which it is most important to understand; and on this subject our knowledge has been rendered much more satisfactory and precise by the observations of Dr. Currie, and by the practitioners who followed his directions as to the use of cold in febrile diseases. From those obser-

vations it may be stated, as a general result, that the morbific effects of cold depend, not simply on the temperature applied, nor on the suddenness of the application, nor on the previous heat of the body; but on the intensity and duration of the sensation which is produced by its application, and especially on the circumstance which primarily determines the duration of that sensation, viz. the facility with which, from the previous state of the system, the circulation on the surface of the body is checked and depressed.

In regard to the Morbid Poisons, which excite diseases often of the most virulent and appalling character, but confined to certain seasons or localities, there has been much and often violent discussion within the last forty years; during which time the contagious nature of the fever of this climate, of yellow fever, of plague, of purulent ophthalmia, of erysipelas, dysentery, and malignant cholera has been successively and freely agitated; the laws of the origin and diffusion of the malaria producing intermittent and remittent fevers have been investigated; and the extraordinary protection against small-pox afforded by vaccination has been first established as a general law by the observations of Jenner, confirmed by others in all parts of the world, and afterwards ascertained to be subject to limitations, the exact amount of which is still doubtful.

Perhaps the most important results of the labours bestowed on these important subjects are the following:—

1. The contagious nature of the common continued fever of this country has been firmly established; at the same time the truth of the representations of the older authors, as to the variations to which this disease is liable at different times and places, in duration, in symptoms, in the effects of different remedies upon it, and the extent to which these can be borne, and in the degree of its contagious property, has been fully and repeatedly demonstrated.

2. The influence of the most important auxiliary causes which favour the extension of this disease,—the cold weather of this climate, imperfect nourishment, and mental depression,—has been fully exemplified and repeatedly observed, particularly in the disastrous history of various military enterprises, and in the equally melancholic civil history of one unfortunate portion of the British dominions:* whether these circumstances of predisposition ever suffice for the generation of the disease, without the aid of a specific contagion, is perhaps still doubtful.

3. It has been well ascertained, particularly by the researches of Dr. Bancroft, that neither the accumulation of human effluvia from healthy persons, nor the effluvia from putrid animal and vegetable matters, (however injurious to the strength, and in various ways to the health, of the human body,) are a sufficient cause for the production of contagious fever.

4. Several of the conditions which appear chiefly to favour the development and propagation of the malaria, which is the other great cause of fever, have been sufficiently investigated, perhaps more successfully by Dr. Ferguson, (Edinb. Philosophical Transactions, vol. ix.) than any other author. It appears certain that the stagnation, and subsequent evaporation of water on the earth's surface are essential to the development of this poison, and that the higher the temperature at which this evaporation takes place, the more violent is the poison generated. It is very doubtful whether any putrescent matter is necessarily connected with its formation; but it must be admitted that there is some condition necessary to that process, which is still unknown, and that we must still be guided in a great measure by experience, in judging of the situations where it is chiefly to be apprehended. [From all the writer's observations, it would not seem to be either of animal or vegetable origin, but to be geological, or connected with locality.]

5. It has been clearly ascertained that the contagious fever of this climate, which usually abates during the summer, is seldom or never met with in the tropical climates; and this fact seems to be illustrated by the important observations of Dr. Henry, by which it appears that the contagious effluvia of the exanthemata, as well as of typhus, loses all its efficacy at the temperature of 140° or even 120°. On the other hand, it is certain, that the fever from malaria is greatly aggravated in these climates, and takes, occasionally, quite the form of the most malignant Yellow Fever. [Yet there would seem to be a marked difference between yellow fever and those fevers that are commonly regarded as malarious—intermittent and remittent, for example.] It has been ascertained, also, that the worst epidemics of that kind, which have so frequently appeared in certain localities in the hot climates, are generally to be ascribed to certain local causes, and are confined within certain limits or boundaries; so that among those who keep beyond these limits the disease hardly ever spreads, whatever the intercourse of persons already affected with others may be; as has been repeatedly exemplified at Gibraltar, New York, &c.; but it is still doubtful whether, within these limits, and at these times, the worst form of the yellow fever does not spread by contagion.

6. It has been equally demonstrated that the Plague spreads by contagion chiefly, if not exclusively, although with very various rapidity on different occasions; and that precautions to prevent the intercourse of the sick with the healthy are more certainly efficacious in checking the ravages of that than any other epidemic disease; as has been repeatedly found in the experience of the British colonies in the Mediterranean, as well as of the army in Egypt. [Still, many observers deny its contagious nature].

7. It has been shown, to the satisfaction of the greater number of medical men who have seen the diseases prevailing epidemically, particularly in civil life, that the purulent ophthalmia is a contagious disorder; and that erysipelas and dysentery do also occasionally spread by contagion; but it has also distinctly appeared that completely isolated cases of the two last diseases, occur so much more frequently in some seasons and countries

* It is gratifying to be able to state that the members of the *medical* profession in Ireland cannot be charged either with want of zeal to alleviate the distresses of their countrymen, or with want of judgment and intelligence, in attempting to draw from these distresses, themselves, lessons of the highest importance to posterity.

than in others, that there must be some cause, not yet understood, corresponding to the idea usually affixed to the term "epidemic or atmospheric influence," which aids in determining many attacks of these diseases.

8. The numberless observations which have been made, in so many different quarters of the globe, on the diffusion of the malignant cholera, have still left such an obscurity on that point as clearly to indicate that the mode of extension of that "nova pestis" must be very peculiar. The present writer has no difficulty in expressing his own conviction that the disease has a contagious property; which conviction is founded simply on the repeated observation of persons who had intercourse with those ill of the disease, becoming themselves affected in a proportion infinitely greater than those, similarly circumstanced in other respects, who avoided such intercourse. But, on the other hand, it is equally certain that in various instances, where it has prevailed epidemically, this superior liability of those holding intercourse with the sick has not been observed; it has affected so many, in whom no such intercourse could be ascertained, or appeared possible, and has left unaffected so many others, whose intercourse with the sick had been frequent and close,—that we can hardly suppose contagion the only mode in which it can diffuse itself.

It may be added, that whatever be the true origin of the poison which generates the cholera, it certainly possesses in an extraordinary degree the properties, which all other morbid poisons possess in some degree, of lying latent for a length of time,—in certain localities, or in the constitutions of individuals, or in both,—and afterwards resuming its activity and rapidly extending itself, without any assignable cause.

The additions which have been made to our knowledge of the nature and proper treatment of diseases during the time under review, may be traced, for the most part, to the extent and minuteness with which the study of morbid anatomy has been cultivated. The example of Baillie, in London; the lectures of the late Dr. Gregory, in Edinburgh, (who, although not deeply learned in morbid anatomy, was keenly interested in the subject, and took every opportunity of inculcating its importance;) the laborious researches of Abercrombie and others, have had much influence in extending this study among British practitioners; but we must admit that it is to the zeal of the profession in France, and to the opportunities afforded by the French hospitals, that we are chiefly indebted for the increased extent and precision of our knowledge of the changes of structure effected in the human body by disease.

This study has, indeed, engaged so much attention of late years, that the term pathology has very often been used as synonymous with morbid anatomy; as if there were no other sources, from which we could draw our knowledge of the changes in the living body, constituting disease, than the changes in the dead body which disease leaves behind it. This, however, is a manifest error in science. These alterations in structure produced by disease are only one of the elements of our reasoning on the nature of diseased actions themselves; and there are many other facts, as to the external causes of diseases, the nature of their leading symptoms, their consequences, local and general, in the living body, and the *juvantia* and *lædentia* affecting them, which likewise furnish the proper elements of inductive reasoning, for the determination of those laws of the animal economy, which it is the object of the science of pathology to establish.

It is also an important practical error to fix the attention, particularly of students of the profession, too much on those characters of disease which are drawn from changes of structure *already effected*, and to trust too exclusively to these as the diagnostics of different diseases; because in many instances these characters are not clearly perceptible until the latest and least remediable stages of diseases; the very object of the most important practice in many cases is to *prevent* the occurrence of the changes on which they depend; and after they are established, the cases are very often hopeless, or admit only of palliative treatment. In those diseases in which most can be done by art, our practice must always be guided in part by conjecture, because, if we wait for certainty, we very often wait until the time for successful practice is past; and therefore, although an accurate knowledge of the whole history of each disease is essential to its proper treatment, yet in a practical view the most important part of its history is the assemblage of symptoms, by which its nature at least, if not its precise seat, may often be known, before any decided lesion of structure has occurred. Accordingly, when this department of pathology is too exclusively cultivated, the attention of students is often found to be fixed on the lesions to be expected after death, much more than on the power and application of remedies, either to control the diseased actions, or relieve the symptoms, during life.

But although in this, as in other instances, there has been an admixture of error, if not in our scientific acquisitions themselves, at least in our estimate of their value, and our judgment of the uses to which they may be applied, yet it is evident that the department of morbid anatomy is that in which the grand improvement of medical science has lately been effected; and that it is from judicious reasoning on the more intimate knowledge thus acquired of the nature of diseases, that any material improvement in the precision of our practical rules has resulted.

These observations apply particularly to the case of inflammatory diseases, those in which remedies avail the most, and with the history of which, therefore, it is most important to be familiar.

The characteristic effects of inflammation, adhesion, suppuration, ulceration, and gangrene, have been investigated with great acuteness and success by Mr. Hunter and his followers, among whom Dr. Thomson, of Edinburgh, [Professor Alison himself, Dr. Macartney, of Dublin, and Dr. C. J. B. Williams,] may be particularly noticed; and the provisions of nature for the favourable terminations of all these processes are now well understood. The nature of the process of inflammation itself has been carefully scrutinized, in so far as microscopical observations avail in the re-

search, by Drs. Wilson Philip, Thomson, Hastings, and Black; and more lately by Andral, Gendrin, Kaltenbrunner, [Magendie, Gulliver, W. Addison,] and others. It may be confidently asserted that these observations have proved the inadequacy of any explanation of the process, which turns merely on the changes in the contractile power of the vessels concerned. It was, indeed, clearly perceived by Mr. Hunter, that changes in the vital properties of the blood itself must necessarily be taken into account, in attempting any explanation of inflammation and its consequences: and the inquiries of the three last-mentioned continental authors, of Schröeder van der Kolk, Pring, Rogerson, and others, have opened a prospect of some more definite information being acquired as to the nature of the essential changes which these vital properties undergo during these processes. [See a Report on the Present State of Knowledge of the Nature of Inflammation, by Mr. T. Wharton Jones, in *Brit. and For. Med. Rev.* for April, 1844, p. 567.]

But the most important recent additions to our knowledge of inflammatory diseases have been the accurate observations made on the varieties of inflammation, and consequently increased precision of our views as to the different *modes of fatal termination* to be apprehended in different inflammatory diseases; and these may be considered under several distinct heads.

1. Much has been done in regard to the different course and effects of inflammation, as it affects *different textures* of the body; and the fact has been established, that even in its acute, and still more in its chronic form, inflammation frequently spreads extensively, lasts long, and produces decided lesions in one texture, without in the slightest degree affecting others in its immediate neighbourhood. Repeated observations on the bodies of those who have died of pleurisy, of bronchitis, of peritonitis, and of dysentery, as well as of more external inflammations, leave no room for doubt on this point. Formerly the diagnosis of different inflammatory diseases seldom extended farther than the *organs* chiefly affected, and the functions of which were deranged; but we now consider the *texture* primarily affected to be one of the most important objects of inquiry, and to be frequently within the reach of careful scrutiny.

The variety in the course and effects of inflammation to be expected in different textures,—in the cellular, serous, fibrous, and mucous membranes, in the different parenchymatous viscera, the muscles, bones, &c. was first pointed out as a particular object of attention by Bichat in France and Dr. Carmichael Smyth in England; its importance was strongly inculcated by Dr. Gregory in his lectures; and our knowledge of these varieties in the different parts of the body, and of the symptoms by which the attacks of inflammation in the different textures may, in general, be first distinguished, has been greatly extended and improved by many other authors,—by Thomson, Abercrombie, Pemberton, Brodie, Travers, Hastings, and others in this country; and by Pinel, Corvisart, Bayle, Laennec, Rostan, Lallemand, Andral, Louis, &c. in France. The distinction of the different species of inflammation attacking the eye, and the accurate anticipation of the danger of each by all the recent writers on the eye, furnish a beautiful example of the increased precision which the attention to variety of textures has given to pathology.

Farther, not only the effects to be expected from inflammation in the various textures have been ascertained by dissections, but characteristic *symptoms* resulting during life from these consequences of inflammation in several parts of the body, not open to ocular inspection, have been clearly pointed out by recent authors.

This is remarkably the case in regard to inflammations within the chest. The lesions resulting from these, as well as other organic changes in that part of the body, may certainly be very frequently ascertained by manual examination, and by auscultation and percussion, according to the methods of Laennec, with a precision formerly unknown. The usual effects of the inflammation of the pleura, and of the bronchiæ, may almost always be recognised and distinguished by percussion and auscultation; and there are many instances of these diseases occurring without any complication, which might formerly have been confounded under the general term pneumonia, and which it is not only satisfactory, but practically important, even in their later stages, to distinguish, because they admit of relief from different modes of treatment. There is, in general, more difficulty in forming a judgment as to the existence or extent of inflammation in the substance of the lungs; for this inflammation is very frequently combined with others within the chest; and although the "râle crepitant" and the "peripneumonic sputa" are occasionally well marked and characteristic symptoms, yet they are by no means to be depended on as constant symptoms. The effects of inflammation, either of the external or internal surface of the heart, frequently show themselves unequivocally, on auscultation and percussion, and by the increased action and obvious enlargement of the heart resulting from them; but there are cases, particularly of the former, where much injury may be done, without such indications clearly presenting themselves, even to the most experienced observer.

One important result of the recent observations on the effects of inflammation within the chest is, the ascertained rarity of circumscribed collections of pus in the substance of the lungs, and the frequency of such collections exterior to the pleura; the established easy diagnosis of the two kinds of Empyema, the one with and the other without pneumothorax, from fistulous communication with the bronchiæ; and the distinction of the former class of cases of empyema, according as the communication has been opened from without inwards, in consequence of ulceration of the diseased pleura, or from within outwards, in consequence of tubercular disease and ulceration of the lungs; the former of these two cases admitting sometimes of gradual cure, the latter being only an accident in the course of incurable phthisis.

Another important addition to our knowledge of thoracic disease is the discovery of the frequency, and explanation of the nature, of the change called Emphysema of the Lungs, as a consequence of long-continued Bronchitis, particularly when combined with spasmodic Asthma.

All these improvements, as well as the original discovery of the application of the sounds heard in the chest to the diagnosis of its diseases, are to be ascribed chiefly to the industry and acuteness of Laennec.

The occurrence of inflammation of the Larynx and glottis in adults, tending to a fatal termination, by mere thickening of the membrane, by effusion of pus behind it, or by the œdema glottidis, without the formation of the false membrane of croup, is an important fact ascertained by the observations of Baillie, Farre, Lawrence, and many others; and the diagnosis of the cases of the kind in which the bronchi are unaffected, and an operation promises relief, is another advantage which the new methods of examining the chest afford.

The existence of inflammation of the Mucous Membrane of the great Intestines in all cases of dysentery, and of inflammation of the same membrane of the small intestines in a certain class of cases of diarrhœa, the diagnosis of inflammations of this membrane from those of the peritoneum, its remarkable tendency to ulceration, its frequent (though by no means uniform) combination with inflammation of the liver, particularly in the hot climates, and with continued fever in this climate, and the indications of its degree, and of its stage, to be drawn from examination of the stools, are important additions to our knowledge of abdominal inflammations, which we owe to the labours of Somers, Ballingall, Johnson, Robertson, and many other military and naval practitioners,—of Abercrombie, Cheyne, Harty, and others in this country, and of Petit and Serres, Broussais, Andral, Chomel, Billard, &c., in France. The instantaneous change of symptoms, violent pain, and rapid sinking, which succeed the perforation of intestine by an ulcer beginning in the mucous membrane, and effusion of feculent matter on the peritoneum; the correspondence of this accident to the perforation of the pleura in phthisis, and the evidence, thence resulting, of variety of endowment of the serous and mucous membranes, are striking illustrations of the increased precision of our pathological information.

The varieties of inflammation within the Head, and of its results, have likewise attracted particular attention, chiefly since the publication of the writings of Lallemand and Rostan on the softening of the brain, certainly one of the effects frequently produced by inflammation there. The inflammation of the membranes may often be distinguished, by the acuteness of the symptoms, in its earlier stages, from that of the substance of the brain. Much more minute diagnostic marks have been proposed by the authors just named, by Bouillaud and others; but subsequent observations have shown that on these no great reliance can be placed; and in fact, as the only symptoms which can yet be relied on, as indications either of inflammatory effusion or disorganization within the cranium, are affections of sensation or voluntary power, and as these result only from changes at the base of the brain, therefore generally in parts at some distance from the actual seat of disease, and the affection of which may be said to be accidental, it is evident that there may be great variety in the symptoms, independent of varieties in the diseased states themselves; and accordingly, we cannot with any certainty anticipate either the nature or the exact seat of the effects of inflammation within the head, from any symptoms or combinations of symptoms;—all that we can pretend to distinguish (and that not with absolute certainty) is the period of the disease when the symptoms no longer depend on the inflammatory action itself, but chiefly on effusions or disorganizations consequent upon it, and continuing after it has subsided.

2. The distinctions of inflammatory diseases according either to the organs or textures affected, and the usual effects produced in these, are not the only distinctions of practical importance in that class of diseases which have been elucidated by modern pathologists. A very important class of their observations relates to cases which, although running the usual course, and often with even more than the usual rapidity, are concealed or rendered *latent* by peculiarity of constitution, and can only be recognised with certainty by such unequivocal local indications of effusion or disorganization, consequent on inflammation, as those to which allusion has just been made. The circumstances in which these latent inflammations are most to be apprehended (which are in general those in which the system is much weakened, the quantity of blood lessened, and the sensibility blunted, as in the last stage of fever or of some of the febrile exanthemata,) are very important to be known, because, in some such cases, if the practitioner is on his guard, he may detect their existence while it is yet time to apply remedies.

Again, many important observations made by modern pathologists have given precision and authority to the statements of older writers, as to inflammations occurring and producing exactly their characteristic effects in various parts of the body, but running their course so slowly, as to take the form of *chronic* instead of acute disease; as in the case of cold or chronic abscess on the surface of the body; chronic pleurisy leading to extensive empyema, without either acute pain or inflammatory fever; partial inflammatory induration of the brain, or hepatization of the lungs confined to individual lobules, &c. The knowledge of this form of inflammation is obviously important, as suggesting and justifying a corresponding modification in the use of the usual antiphlogistic remedies.

The term Sub-Acute Inflammation has also been properly applied by Dr. Armstrong and others to a form of truly inflammatory diseases of various textures, where not only the symptoms, general and local, are milder, but the local consequences which show themselves much less extensive than in the more decided and acute cases, and the amount of depletion necessary to avert danger is much less, while at the same time there is no such extension of the period of the disease as to justify the use of the term chronic.

3. What makes it peculiarly important to attend to these varieties in the intensity and duration of strictly inflammatory disease, even in the same parts of the body in different individuals, or at different times in the same, is the obvious application of this principle to other cases, where the symptoms are in the first instance those of

inflammation, but the ultimate result is the establishment of other forms of disease, which have been often regarded as quite distinct from, or even incompatible with inflammation. Of this the most striking example is in the case of Dropsy, or serous effusion in various parts of the body, the connection of which with inflammation has lately been the subject of much inquiry.

The lectures of the late Dr. Gregory, and the writings of Rush, of Cheyne, of Abercrombie, [of D. Davis,] and others, have satisfied the great majority of practitioners in this country, that the acute Hydrocephalus of Cullen is to be regarded in general as an inflammatory disease, although in many fatal cases no other effect of the inflammatory action can be found than the serous effusion into the ventricles; and the cases recorded by Blackall, by Abercrombie, by Crampton, and many others, have also shown that there are many cases of general dropsy, beginning, or repeatedly renewed, by inflammatory attacks, and admitting of great relief from a certain extent of bloodletting, generally premised to, or combined with, the purgative or diuretic medicines. This practice, which had been repeatedly adopted by various practitioners, and again fallen into disuse, has been put on the proper footing by numerous dissections, which have shown the very frequent complication of dropsical effusion with repeated inflammatory attacks, (often of the sub-acute or chronic character, but known by their usual products,) in the heart, lungs, liver, or kidneys; while, at the same time, these observations sufficiently demonstrate that any great extent of dropsical effusion is hardly ever the effect of inflammation *alone;* that some more permanent lesion of these parts is usually likewise present; and that even when partly or chiefly dependent on inflammation in its origin, the effusion is very generally persistent long after this cause has disappeared.

Nor is dropsical effusion the only form of disease, usually regarded as chronic, to which we may confidently assert, (trusting to the information acquired by recent pathologists,) that inflammation may give rise, or into which it may graduate. Attentive observation shows that many of those organic changes of structure which are commonly called Obstructions in the more important viscera, whether combined with dropsical effusion or not, appear frequently to originate from the causes of inflammation, to be attended with some of the first symptoms of inflammation, and to combine themselves with, or graduate by insensible degrees into, the acknowledged effects of inflammation. It is true that in many other cases their invasion is quite gradual and insidious, and there is no evidence of more than mere "perversion of nutrition" in their development; and that such organic alterations of texture likewise differ essentially from the simple effects of inflammation, in being hardly at all liable to absorption, to which the simply inflammatory effusions are peculiarly prone; it is clear, therefore, that in every case there must be some condition, independent of inflammation, necessary to their production; yet the inference from the former class of facts is still a fair one, that an inflammatory action, generally of the sub-acute or chronic kind, is, in many cases, *one of the conditions* on which their growth depends. These points have been keenly discussed of late years by the French pathologists, particularly Broussais, Laennec, and Andral; the first of these authors certainly attributes too much to the "phlegmasies chroniques" as the cause of all chronic diseases; the second probably too little; and the conclusion now stated seems to agree very nearly with the opinion of the last, who is generally thought in this country the best informed and most judicious of the present French pathologists.

[Of late, however, by many pathologists, as by Papavoine, Fabre and Constant, Gerhard and Rufz, Piet, Barthez and Rilliet, and others, the acute hydrocephalus of authors has been regarded as tubercular meningitis, the tubercular matter being deposited in the meshes of the pia mater; and many of the cases classed under hydrocephalus are, unquestionably, of this character.]

Of those cases of visceral organic disease, often connected with dropsy, and often originating in inflammatory action, there is one, the frequency of which was not suspected, and the indications of which were not understood, until very lately,—viz. the granulated or tuberculated state of the secreting portion of the Kidneys, first ascertained by Dr. Bright to be the almost inseparable concomitant of the albuminous state of the urine, which had been previously noticed by Dr. Wells, Dr. Blackall, and others, in many cases of dropsy, but which exists also, not unfrequently, without any dropsical symptom.

This discovery is the more important, as the effect of the diseased condition of the kidneys is to alter the nature and diminish the quantity of one of the great excretions from the body; from which results, as the experiments of Dr. Christison and Dr. Bostock, [Rayer, Martin Solon and others,] have shown, a palpably diseased condition of the blood, and an undoubted example, therefore, of the kind of morbid changes to be apprehended from such a cause. All that has yet been ascertained on this point is this, that when the urine is albuminous, and its specific gravity low, and the serosity of the blood therefore unnaturally loaded with urea, or extractive matter resembling urea, the health is always precarious, inflammatory diseases of different parts are apt to occur, and organic disease, particularly of the lungs or brain, frequently supervenes; and that in the last stage of such disease, when the secretion is almost suppressed, slight febrile symptoms rapidly advancing to coma, as in the true ischuria renalis, have been repeatedly observed.

Again, the tendency of inflammation, when it occurs in particular constitutions, to pass into, or give origin to, organic disease, is thought by many pathologists to be remarkably exemplified in the case of scrofulous Tubercles, and to be one of the principles, regarding the origin of that very frequent and fatal form of organic disease, which it is most incumbent on the practitioner, with a view to the prevention of such diseases, to have constantly before his eyes. On this point likewise there has been lately a difference of opinion both among French and English pathologists; and it is evident that tubercles frequently originate without either the causes or the indications of inflam

mation showing themselves; and that the distinctions between tubercles and the usual effects of inflammation (particularly as to the subsequent liability to absorption) are such as to show, that they can in no case be ascribed to inflammation as their sole cause. But when all these admissions are made, it may still be held as a principle of the highest practical importance, that in certain constitutions or in certain circumstances, an inflammatory attack, if not very speedily remedied, is very likely to act as the immediate cause of a deposition of tubercles, and consequent chronic and nearly hopeless disease.

The nature of the peculiarity of constitution, which disposes to this rather than other consequences of inflammation, is in all probability to be sought in the composition and vital properties of the blood; and some of the microscopical observations of Gendrin, (particularly that of the presence of translucent globules in the fibrinous effusions of healthy inflammation, and their absence in incipient tubercles,) seem to afford a fairer prospect of successful investigation of this point than any former observations had given. In the mean time the external causes, which particularly favour the development of that constitutional peculiarity, and especially the relative efficacy of climate and of impure air, imperfect nourishment, and deficient exercise, during childhood and youth, in producing it, have been illustrated by statistical inquiries, of the kind formerly mentioned, which are necessarily much more valuable, in this view, than the records of the experience of any individual.

Besides the connection of inflammatory action with various forms of organic disease, of which we have thus spoken, much stress has been laid by some recent authors on increased determinations of blood, approaching and sometimes amounting to inflammation, as a main cause of many chronic diseases which are merely *functional*, e. g. of neuralgic pains, of different spasms, of dyspepsia and other effects of deranged secretions in the primæ viæ. This speculation has pretty certainly been carried too far by some, particularly by Broussais and his followers in France, and by the late Dr. Parry in this country. In many such cases it seems certain that the increased determination of blood is the consequence, not the cause, of other derangements of vital action; yet that it often occurs and aggravates the evil, and affords a fair indication for practice, seems well ascertained; and the remarks of Dr. Parry on the beneficial effects of spontaneous hæmatemesis in some cases of urgent dyspepsia, and the accurate observations of Dr. Wilson Philip on the effects of local bleedings in what he calls the second stage of dyspepsia, may be quoted in proof of this position.

4. Another important set of observations on inflammatory diseases consists of those which have been made on the characters, and progress, and peculiar dangers of Specific Inflammations resulting in general from particular causes only, and differing from the usual form of inflammation in the nature of their local symptoms and effects, or in the character of the accompanying fever, or in both these particulars.

The distinction of Phlegmonous and Erysipelatous inflammation in external parts, as well as of the specific cutaneous inflammations of the exanthemata, had indeed been long known, and our knowledge of the great variety of inflammations affecting the skin has been greatly extended and corrected, particularly by the labours of Willan and Bateman. But even Dr. Cullen, who referred the erysipelas, with great propriety, to his class of Exanthemata rather than Phlegmasiæ, and considered the fever attending it as by no means symptomatic of the inflammation, but as resulting from a cause acting in the interior of the system, and of which the inflammation was likewise an effect, had not a correct view of the peculiarity of the inflammation itself. He supposed that peculiarity to depend merely on the texture affected; the true skin being, according to him, the seat of this inflammation, while the phlegmon is seated in the cellular membrane. He did not advert to the circumstance, that the *disposition to spread* along the surface, and the *deficiency of organizable lymph* in the inflammatory effusion, were local symptoms equally peculiar and characteristic of this inflammation, as compared with other inflammations of the same texture, as the priority of the febrile symptoms, and their frequently typhoid character; and therefore did not form the notion which French pathologists annex to the term *specificité*, as applicable to this form of inflammation.

Subsequent inquiries have, however, distinctly shown, that this principle is of real and great importance, as applicable both to this and other inflammations. It appears from the researches of the late Dr. Duncan, of Mr. Travers, Mr. Lawrence, Dr. Butter, and others, that when this inflammation extends from the skin to the *cellular membrane*, as so frequently happens in erysipelas, it preserves the same local characters in the latter texture as in the former; that in some cases this kind of *diffuse* inflammation affects the cellular membrane extensively without extending to the skin; that it often prevails epidemically, and is certainly sometimes propagated by contagion or inoculation; that it may arise from different peculiar causes, of which the most frequent seems to be the introduction into the system of some kind of animal poison, as in the case of poisoned wounds from dissection: that in this as in other cases, when such a poison acts on the body, a peculiar derangement of the nervous system and depression of the vascular system are very often observed, giving to the fever attending such inflammation the character to which we apply the term Typhoid; and that there is frequently a danger from this form of fever, quite independent of that which the local inflammation could effect; and not to be remedied, sometimes even to be aggravated, by the use of means for subduing that local inflammation.

Farther, it seems well ascertained that on internal membranes, and sometimes in connection with this erysipelatous inflammation on the surface, there are examples of a similar *diffuse* form of inflammation, tending to serous and sero-purulent effusions chiefly, not to exudations of organizable lymph, and that the fever attending this inflammation is more or less perfectly *typhoid*; and the danger resulting from it so little in proportion to the intensity or duration of the inflammation,

that in the most rapidly fatal cases the inflammatory appearances found on dissection are generally the least obvious.

Such examples of internal erysipelatous inflammation may in some instances be pretty certainly distinguished from the more usual form of inflammation in internal parts; they have been most decidedly observed in the peritoneum; and the epidemic and contagious Puerperal Fever, although not the only case of the kind, is that to which the foregoing remarks most particularly apply; but in this as in other contagious diseases, there appears to be great variety, in different epidemics, particularly as to the extent to which the inflammation goes, and to which the remedies for inflammation may be safely carried.

These statements appear to be fair deductions from the facts stated on this subject by Armstrong, Hey, Mackintosh, Campbell, and others, who have witnessed extensive epidemics of this kind, particularly when compared with the cases of this form of peritonitis, (sometimes evidently in connection with erysipelas,) recorded by Dr. Abercrombie, and with several that have fallen under the observation of the present writer.

There is strong reason for thinking that there is something equally peculiar or specific in the inflammation of Dysentery, when it prevails epidemically, and when it extends itself (as the writer is satisfied he has occasionally observed) by contagion; and it seems quite certain that a peculiar spreading inflammation of the mucous membrane of the fauces, tending to a peculiar aphthous exudation on its surface, and attended with a dangerous typhoid fever, sometimes prevails epidemically, as in the experience of Dr. Bretonneau of Tours, who gave it the name of Diphtherite.

In all these cases it may be at least reasonably conjectured that a peculiar animal poison is either introduced into or generated in the blood, which circulates through the system, and by its depressing or sedative influence causes the peculiarities, both in the local and the general symptoms, and progress of the disease, which distinguish it from simple or *healthy* inflammation of the same parts. It is an important observation, first put in a clear view by Mr. Travers, that a similar peculiarity is given to the *general* symptoms resulting from external injuries, by the influence of a violent concussion or shock, affecting the system at the time when such local injuries are received; but it may be doubted whether the term Irritation, applied by him to the constitutional affection, either from such injury, or from specific inflammation, is the best that could have been chosen. The rapidly spreading Traumatic Gangrene described by Larrey and others seems to be an effect produced in some cases on the local inflammation consequent on a violent injury, by the concussion which has such an influence on the constitutional symptoms; and indeed more or less of gangrene or sloughing is always to be apprehended from inflammation excited in a system where the powers of the circulation are remarkably depressed.

That an animal poison, circulating and multiplying itself in the blood, is an adequate cause both for the local peculiarities and for the peculiar typhoid symptoms, attending the specific inflammations above noticed, appears pretty certain, not only from the analogy of the contagious exanthemata and their communication by inoculation, but also from what is observed as to the effects of inflammation affecting the lining membrane of veins, where much of the inflammatory effusions must necessarily be mixed with the circulating blood. In this case, even although the vein has inflamed from a simple injury, without evidence of any specific cause having been applied, such typhoid symptoms, according to the observations of Hunter, of Travers, James, Arnott, and many others, seem almost invariably to occur. Indeed, as the veins of the uterus have been found inflamed in several cases of puerperal fever, it has been suspected by Dr. Lee that that disease may be generally dependent on this cause.

Another observation which has been made on cases of inflammation of the veins, by Mr. Arnott and others, is likewise of great importance. It has been found that this inflammation is very frequently followed by rapid inflammation, and still more rapid purulent depositions in distant parts, particularly in the cavities of joints, or in the internal cavities; and it seems probable that it is in this way that we are to explain the occurrence of such rapid inflammation and suppuration in internal parts, particularly the Liver, which has been often observed after severe injuries of the head or other parts of the surface.

This observation ought evidently to be taken in connection with another, made by many recent authors, by Guthrie, Rose, and others in England, and by Dance, Velpeau, &c. in France, of the frequency of internal inflammation, going on with extreme rapidity to deposition of purulent or tubercular matter in internal parts, immediately after the amputation of a limb, where such formations from the blood had been previously established; and both observations should be taken in connection with the facts, which seem established by the researches of Velpeau, Kaltenbrunner, Gendrin, and others,—*first*, that the veins leading from extensive collections of matter, especially in chronic cases, are often found loaded with pus; and, *secondly*, that the conversion of globules of blood, or of fibrine, into pus, takes place not only in extravasated effusions, but *within the vessels* of parts in a certain stage of inflammation.

The inference from all these facts appears to be, that purulent matter generated in the human body itself, if by any means it is caused to circulate in the blood without finding a ready outlet, disposes not only to peculiar febrile symptoms, but also to inflammation of a peculiar character, which goes very rapidly to extensive suppuration, in whatever part may be most prone to such disease; and this is evidently an important addition to our knowledge of Specific Inflammations, and is applicable, as will presently appear, to several cases of the most important chronic diseases.

The inflammation of Syphilis is another example of specific inflammation resulting apparently from a morbid poison circulating in the blood, and falling on particular textures; and in regard to the several points of great importance seem to have been ascertained by the observations of Abernethy, Pearson, Rose, Guthrie, &c. in London, of Carmichael in Dublin, of Dr. Thomson in Edinburgh, [of Ricord of Paris,] and others, par-

ticularly the variety of its forms and progress in different individuals even at the same time, and the more gradual change of the character of the disease and malignity of the virus in the progress of time; the fallacy of the old opinion that in any of its forms (as they now present themselves) the disease is absolutely void of natural tendency to a favourable termination; the variety of treatment which its different forms demand; the frequent combination of syphilitic inflammation, either with healthy inflammation on the one hand, or with scrofulous disease on the other; the aggravation of the disease, in either case, which may result from the use of mercury; and the proper restriction of the virtues of this medicine, in regard to syphilis, to the character of an *alterative* rather than an *antidote*.

The inflammation of Gout is another to which the term Specific is properly applied; and the important discovery of Dr. Wollaston, of the existence of uric acid in the concretions which result from long-continued gouty inflammation, at once tends to explain the known connection of gout with the calculous diathesis, and connects this with the other specific inflammations dependent on a morbid matter in the blood.

The inflammation of Rheumatism may also be held to be strictly specific, although the existence of any peculiar ingredient in the blood cannot be ascertained. That there is something peculiar in the vital constitution of the blood in this disease appears, however, to be rendered highly probable by the nature of the peculiarities that most remarkably distinguish it; by the tendency to affect different parts and textures in rapid succession; by the total absence of suppuration as an effect of this inflammation; by the apparently increased proportion of the fibrine, and complete separation of it from the red matter in the blood drawn, and by the remarkable proportion of fibrine in the exudation produced by this inflammation when it affects the heart. The frequency and danger of the affection of the heart and pericardium in this disease have been completely established by the observations of Pitcairn, Dundas, Wells, Davis, Abercrombie, and others, and is one of the important additions lately made to Pathology. The circumstances in which it is most to be apprehended are by no means so clearly made out; but the writer has no difficulty in stating his conviction, that large and repeated bleedings in the beginning of rheumatism increase the risk of this metastasis; and in assenting to the observation of Dr. Elliotson, that after it has occurred it is more properly met by local than general bleedings. The labours of Willan and Bateman have been more successful than those of any others in distinguishing the many different forms of inflammation (particularly chronic) to which the skin is liable, but the classification of these diseases, which they have attempted, is more formal and precise than the nature of these ever-varying forms of disease will justify.

5. The great improvements which have been thus effected in our knowledge of the history and varieties of inflammatory diseases are of practical importance in the treatment of such diseases, not by suggesting new remedies, but chiefly by giving us more precise information than we could otherwise have had, of the particular danger which is threatened in each case of such diseases, and of the particular symptoms indicating such danger; and thus guiding us as to the proper time and the proper extent of the application of those, which we already possess and understand. Many attempts have been made, during the period under review, to add to the number of the general antiphlogistic remedies, or of those adapted to particular inflammatory diseases; and it is generally thought that some important auxiliaries to bloodletting and the other evacuations have been discovered; but it must be owned that there has been no such decided success in this inquiry as in those of which we have already spoken: and although it is right to avail ourselves of these auxiliaries in all cases where evident contra-indications to them do not exist, yet, as a general rule, in the early stage of inflammatory diseases the less that is trusted to them, and the more to the ordinary means of depletion, the better.

This observation may be particularly applied to the use of Mercury in inflammatory diseases, which has been so highly recommended as a remedy for inflammations by Hamilton of Lynn Regis, Armstrong, Travers, and various other practical authors within the last half century, that its virtues might be supposed to have been completely ascertained; but those who are aware of the fallacies attending the observation of the effects of remedies in acute diseases, particularly of such as are only employed as auxiliaries to others of acknowledged efficacy, can easily understand that they may have been much overrated. It has been often represented that not only the purgative mercurial medicines, as general evacuants, and as means of acting particularly on the secretion of the liver, are of peculiar importance, but the action of mercury on the system at large is the surest means of controlling those effusions, and particularly the effusion of coagulable lymph, on which the danger of several inflammatory diseases essentially depends; and in some instances a less defined and more specific virtue in checking inflammation has been attributed to the constitutional affection from mercury. Thus the remedy has been successively vaunted in the case of acute hydrocephalus, of cynanche trachealis, or laryngea, and (generally in the form of calomel and opium) in that of pneumonia, bronchitis, pleuritis, pericarditis, peritonitis, hepatitis, and dysentery; and reference has been often made to the effects which may be observed from it in inflammation of the iris, tending to effusion of lymph there, as demonstrative evidence of its peculiar efficacy.

But it may be stated with confidence, that in the opinion of many of the best informed members of the profession, there has been much exaggeration in all these statements. That there is something very peculiar in the effect of mercury on acute inflammation, particularly of the liver and of the mucous membrane of the bowels, in the hot climates, the numerous and concurrent authorities which might be quoted on the subject leave no reason to doubt; but that any such decided effect can be observed from exciting the specific effects of mercury (marked by its action on the mouth) during the acute stage of any internal inflammation in this country, has certainly not

been established to the satisfaction of most practitioners. That calomel is one of the most convenient purgative medicines in such diseases is certain, and it is equally certain that it is one of the best *corrigents* that can be used along with opium, when the soothing effects of the latter medicine are demanded; because it both corrects its constipating effect, and probably aids in determining its action on the skin, and, when given with opium, much more generally represses than excites vomiting. When given so as to act only in these ways, it may be unquestionably held to be a useful, though not one of the most powerful remedies in inflammatory diseases. But when its action on the mouth has been excited in the course of acute internal inflammation, (which is the only fair way of judging of any specific agency of the mineral on the inflammatory process,) we have not only been very generally disappointed of seeing any improvement of the symptoms immediately follow that change, but are constrained to add that we have more frequently seen an aggravation of them.

In more chronic inflammation, attended with slighter febrile symptoms, or when strictly a local disease, and tending obviously to gradual deposition of coagulable lymph, it is generally allowed that a certain degree of deobstruent rather than antiphlogistic efficacy (unfortunately often inadequate to the evil to be overcome) is attributable to the agency of mercury on the constitution. It is in those cases of syphilis where chronic induration around the ulcers is the most characteristic appearance, that the beneficial action of mercury is in general most distinctly seen; and not only in the case of iritis, but in inflammation of the periosteum, of the larynx, of the liver, perhaps of the peritoneum, when sub-acute or chronic, a similar beneficial influence is sometimes distinctly perceptible. Two cautions, at least in this climate, are, however, certainly important: *first*, that a dysenteric affection of the bowels is often produced by mercury affecting the system; and, *secondly*, that it very often acts as a cause or aggravation of scrofulous disease, in those who have that very common tendency.

Another auxiliary to bloodletting, in inflammatory diseases, particularly in inflammations of the chest and in rheumatism, which has come into pretty general use in this country, is the solution of tartar-emetic, given in frequently repeated and often large doses, but without exciting vomiting. The possibility of patients in inflammatory diseases taking very large quantities of this and many other medicines, particularly if they be not largely bled, without the usual effects of these medicines showing themselves, has been abundantly demonstrated by the experience of Rasori and many other Italian physicians, and of Laennec and his followers in France; but whether there is any peculiar advantage in establishing this "tolerance" of the medicine, and then trusting to a remedy which produces no sensible effects, is a very different question. Under the impressions that we have in this country of the efficacy of bloodletting in acute inflammations, and of the comparative inadequacy of all other means yet proposed, we do not think ourselves justified in placing our chief reliance on this treatment, excepting where the loss of blood is clearly and strongly contraindicated. When bloodletting is pretty freely employed, much smaller quantities of the tartar-emetic than the continental physicians are in the habit of prescribing are found with us to excite and maintain nausea; and it certainly has not been shown, to the satisfaction of the practitioners in this country, that the medicine, in any way in which it can be given without sensible effect, is a more powerful antiphlogistic than when used so as to maintain nausea for hours together. When given in this way, (for which purpose one-third to one-half of a grain every two hours will usually be found sufficient) it is now generally regarded as the most powerful auxiliary to bloodletting in the diseases above-mentioned, and in particular has in a great measure superseded the use of Digitalis as a sedative and antiphlogistic; the general judgment in regard to the last being, that in moderate doses it is inefficient in this view, and in larger doses unmanageable and hazardous.

The colchicum is another medicine introduced within the last twenty years into practice, with the character of an antiphlogistic or sedative rather than an evacuant; and in the case of a fit of gout, the effect of a few doses of this medicine is certainly often more nearly specific than that of any other medicine which we can mention, in an inflammatory disease. But experience, as well as theory, might be quoted in favour of the doctrine, which was keenly advocated by the late Dr. Gregory in his lectures on gout, that the human body always becomes peculiarly liable to other more dangerous diseases, when the attacks of gout are arrested in any other way than by the regimen which corrects the tendency to the disease. The antiphlogistic virtues ascribed to colchicum in other inflammatory diseases are much less generally admitted; but it is generally thought that, by the continued use of this medicine, attacks of acute rheumatism may in many persons be somewhat alleviated and shortened.

A change, and, in the opinion of the present writer, a very material improvement, has taken place within these few years in the judgment of many practitioners as to the use of opium in abdominal inflammations, whether affecting the serous or mucous membrane. It has been clearly shown by Dr. Armstrong and others, that when full bleeding has been premised, opium may be given freely and repeatedly, often with extremely good effect as to the relief of suffering; certainly without any injurious effect on the alvine evacuations, (which seem frequently to be promoted or procured more easily by enemata after the use of opiates;) and it may be pretty confidently asserted, with a considerable diminution of the mortality below what is common when bloodletting and purgatives are the only remedies employed. It is very doubtful, however, whether the notion of Dr. Armstrong, that opiates are here of use by their diaphoretic agency, is the correct one. In the cases which the present writer has observed, the beneficial effect of the opium has been best marked when the pulse has been early much depressed, and has not risen after bloodletting, so that farther loss of blood has seemed hazardous or impracticable. When opium in these circumstances has quickly relieved pain and vomiting,

and procured sleep, the pulse has frequently improved beyond expectation; and a patient who previously seemed quite exhausted has been restored to a state in which farther bloodletting, if required, has been perfectly well borne. That opium, as an auxiliary to bloodletting in these inflammations, can lessen the quantity of blood required to be drawn is very doubtful; but unless the writer is greatly mistaken, it may be confidently asserted that it will enable patients to bear a loss of blood under which they would otherwise have sunk, and thus permit the effectual remedy to be applied repeatedly, and ultimately with success, in cases where it would otherwise have become inapplicable. Of this the writer has been convinced, not only by finding the mortality from the disease under his own observation less since he has given opium freely, (which might have been accidental,) but especially from observing that in the cases which proved fatal under this treatment, the extent of inflammatory appearances found on dissection has always been great and unequivocal; very often indeed these have been complicated with organic disease; whereas, before he adopted this kind of practice, he has repeatedly had the mortification of seeing patients sink early in the disease, in whom the inflammatory appearances found on dissection have been remarkably slight,*—certainly less than must have existed in other cases, where recovery took place. Death in cases of abdominal inflammation does not depend, as in most other internal inflammations, on the lesion of any organ essentially concerned in maintaining the fundamental function of circulation; it results from a sympathetic affection of the circulation consequent on the inflamed state of the intestines; it can be demonstrated that this sympathetic affection is much greater in some persons than in others, suffering under the same amount of abdominal inflammation; and it seems reasonable to suppose, that whatever blunts the intensity of the sensations, produced by the disease in the bowels, and procures ease and sleep to the patient, will lessen the degree of that sympathetic affection of the circulating system. It should always be remembered, (whatever judgment be formed of this or other individual remedies,) that it is not by interrupting the functions of the bowels themselves that acute enteritis is fatal; that restoring the functions of the bowels is therefore only a secondary object, requiring little aid when the main object can be accomplished, and certainly not to be urged as long as there is any risk of the means used to accomplish it aggravating the inflammation. In this respect a useful practical caution may be fairly deduced from the more accurate knowledge we now possess of the causes of death in inflammatory diseases.

The advantage of local bloodletting by punctures or incisions, in those cases of diffused inflammation of external parts, which threaten to be dangerous by extensive suppuration and sloughing, has been established by the observations of O'Halloran, Copland, Hutchinson, Lawrence, Duncan, and many others.

The additions recently made to our knowledge of idiopathic fever may be put in a smaller compass than those which regard inflammation, because the study of morbid anatomy gives us much less assistance in this inquiry, and notwithstanding the amount of labour bestowed on it, much less real and definite improvement has been effected.

It has been ascertained, chiefly by the labours of the French pathologists, but likewise by those of many authors on fever in London, Dublin, and Edinburgh, that the lesions most generally found in fatal cases of what is usually called continued fever, in Europe, are serous effusion in the ventricles and between the membranes of the brain; an increased vascularity, with increased secretion of mucus, on more or less of the bronchial membrane; an œdematous, and often a condensed and softened state of part of the lungs; and thickening, patches of vascularity, and partial ulceration or sloughing, of some part of the mucous membrane of the primæ viæ, especially of the glandular structure there, and most frequently at the lower part of the ileum, often attended with enlargement of the corresponding mesenteric glands. The blood found in the body, or drawn from it during life, very generally, if not uniformly, coagulates less firmly than in health, and sometimes, especially in cases rapidly fatal, is nearly fluid. All other morbid appearances are comparatively rare, and several appearances, particularly congestion of blood in the back part of the lungs and in the mucous membrane lining the depending portions of the intestines, are fallacious; depending on the stagnation of the blood in these parts, both after death and in the extreme stage of debility before death, and on the imperfect coagulation of the blood.

It seems to be also ascertained that the whole of these appearances are seldom found in any one case; that those found are often remarkably various in different individual cases, although a great portion of the symptoms may have been very similar; that although all these appearances are such as occur in decided inflammations, and form part of their character, yet the effusions of coagulable lymph and of pus, which are those most characteristic of inflammation, are very rarely found after fevers, and that after some cases of well-marked continued fever these morbid appearances are altogether absent.

The question that has been most keenly debated of late years, both in France and this country, is, whether all the symptoms of continued fever can be ascribed to the influence of local inflammations in some part of the body, and what is usually called idiopathic fever be thus resolved into symptomatic; or whether fever is a general disease of the system, with which certain local inflammations, sometimes in one part and sometimes in another, frequently combine themselves. The former doctrine has been warmly espoused by Broussais and his followers in France, and by Dr. Clutterbuck, Dr. Mills, and others, in this country; but the opinion of some of the most eminent of the Parisian pathologists, and of the school of Montpellier, and the general opinion of

* It is proper to state that the writer has been oftener disappointed of the effects of opium in acute dysentery than in peritonitis, and that in some cases of the latter disease which he has seen prevailing epidemically, and as he believes spreading by contagion, he has also found it quite inadequate.

the profession in this country, is decidedly in favour of the latter; principally for the following reasons, which, it will be observed, are chiefly taken from the history of the disease as known from observation of the living body, and have been, therefore, too much neglected by those whose notions of pathology are limited to observations on the dead body, and the inferences thence directly resulting.

1. The cases to which we give the name of fevers may be distinguished in practice, and in general without difficulty, if their whole progress is traced, from the other cases in which inflammations of the same parts are found on dissection; by the slighter degree of the local symptoms, as compared to the intensity of the general symptoms; by the greater depression of strength, and particularly the easier depression of the strength of the circulation; by the greater deficiency of secretions, as shown, after some days, by the dryness of the mouth and tongue; by the greater disturbance of the nervous system, and greater prevalence and peculiar character of delirium, generally blended with a peculiar tendency to stupor; by the imperfect coagulation of the blood, or aggregation of the coagulum; and not unfrequently by the appearance of a peculiar cutaneous eruption.

2. The cases of fever, thus characterized, are found to be generally of local and temporary existence among mankind, and are for the most part distinctly referable either to a malaria or a contagion; and thus, in their origin as well as their symptoms, bear an analogy to the effects of certain Poisons on the living body; whereas cases of Inflammation, resembling the effects of injuries or accidents rather than of poisons, occur in pretty uniform frequency in all great communities similarly situated as to climate and habits of life.

3. When the cases, which are thus characterized as fevers, prove fatal, the appearances on dissection are very generally slighter, (particularly in the circumstance already remarked, of the general absence of the most characteristic inflammatory effusions,) than those which we are accustomed to see in the cases to which we give the name of Inflammations; therefore they do not afford so satisfactory an explanation of the fatal event; and occasionally they are altogether absent.

4. The cases thus characterized as fevers, have a much greater tendency to spontaneous favourable termination, than is seen in cases of undoubted inflammation, where the same internal parts are affected, and the same amount of febrile symptoms exists; as is seen in the regular decline of the paroxysms of intermittents, and in the frequent decline of continued fever, with or without critical evacuation, where no active remedies are used.

5. The decline of the cases characterized as fevers very often takes place under the use of stimulating remedies, which are known by experience to be hurtful in similar stages of undoubted inflammations; so that the experience of the *juvantia* and *lædentia* clearly indicates a distinction of these diseased states.

6. When patients recover from the worst stage of the cases characterized as fevers, with little or no artificial evacuation, or under the use of stimulants, experience shows that the health is more perfectly restored, and that there is much less risk of organic diseases succeeding them, than may always be apprehended when recovery takes place from decided and dangerous internal inflammation, under a similar treatment.

[7. The researches of MM. Andral and Gavareit have clearly shown, that in all cases of inflammation, the ratio of the fibrinous element of the blood is augmented, whilst in fevers of all kinds, unless when complicated by manifest local inflammation, it is diminished.]

These considerations would entitle us to regard fevers as specifically different from inflammations, even if certain inflammatory appearances on individual parts of the body attended the general febrile symptoms as uniformly in them, as in the contagious exanthemata; but this conclusion is much strengthened by the fact already stated, that the parts of the body in which inflammatory appearances may be found after death from fevers are remarkably various; and by observation, which may easily be made in such fatal cases, that the only symptoms which can be certainly connected with the appearances on dissection, particularly in the chest or abdomen, are often symptoms occurring late in the disease, and sometimes apparently supervening, from known causes, on the original affection.

In regard to the essential nature of the morbid state, which is thus properly distinguished both in theory and practice, from the effects of inflammation, we cannot say that more progress has been made of late years, than in regard to the essential nature of the progress of inflammation itself. As, indeed, all explanations are founded on comparisons, and as the phenomena in both these cases hardly admit of comparison with any others in nature, it is not to be expected that this investigation can ever be carried far. And as it is generally allowed that fever (both symptomatic and idiopathic) originates in the capillary vessels, i. e. in that part of the living frame which is the seat of the functions hitherto involved in the greatest obscurity, pathologists have been naturally and properly deterred from prosecuting the inquiry, until this department of physiology be farther elucidated. It may be stated, however, that the account given by Hoffmann and Cullen, of the *febrile reaction* consequent on the diminution of secretions and excretions in the commencement of fever, of the increased stimulation of the heart being consequent on obstructed circulation in the capillaries,—may still be held to be so far satisfactory;* but that the idea of a Spasm of the extreme vessels being the immediate cause of that diminution and obstruction, and thereby of the increased stimulation of the heart, has neither been confirmed by any actual observations, nor generally regarded as a satisfactory account of the phenomena; and perhaps the least theoretical expression of what is known on the subject is merely this, that there is, in the commencement of fever, a *deficiency of the vital actions* in the capillary vessels, naturally

* Perhaps the most striking fact which can be stated in support of that doctrine, is the rapid abatement of the symptoms, and shortening of the period of a paroxysm of intermittent fever, observed by Dr. Mackintosh and others to result from bloodletting in the cold stage, which will necessarily lessen the amount of stimulus then acting on the heart.

followed by increased excitement of the heart; and that, in the case of idiopathic fever, this is combined with the peculiar sedative agency of a poison, generated in or absorbed into the blood, the effect of which varies remarkably in intensity on different occasions, and is often very dangerous; although, like that of other poisons introduced into the system, it is essentially transient.

The most important improvement which has been lately effected in our knowledge of idiopathic fever, as in the case of inflammation, may be said to consist in the more accurate discrimination of its Varieties; and the most important of these may be ranked under the following heads;

1. Certain distinctions, of obvious practical importance, have been pointed out as to the intensity and succession of the proper febrile symptoms themselves. The variety described by Dr. Armstrong, Dr. Bateman, and others, under the title of Congestive, though perhaps improperly named, may sometimes be distinctly recognised, both in cases of fever and of the contagious exanthemata; and may be said to be that in which the sedative agency of the remote cause of the disease acts with extreme force, the usual reaction is suppressed or obscured, and the symptoms of the first or cold stage assume their maximum of intensity: the chief appearances being, feebleness of circulation and of muscular strength, coldness of surface, and stupor or confusion of thought, resembling the first effect of concussion of the brain, rather than the usual febrile delirium.

Again, the distinctions drawn by French authors, between the Fièvre Adynamique, in which the weakened state of the circulation, the Fièvre Ataxique, in which the disorder of the nervous system,—and the Fièvre Inflammatoire, in which the degree of febrile reaction,—is the predominant character, although not essentially different from those by which the Low or Putrid Fever, Brain or Nervous Fever, and Inflammatory Fever, had been previously characterized in this country, are yet important, both as familiarizing practitioners to these varieties, and to the causes which may sometimes be assigned for them, and as giving something more of precision to the use of these terms.

[It has been, too, a question of no little importance to determine, whether adynamic fever differs materially in different countries, and at different times in the same country; being frequently, as in the French metropolis, and in the United States, accompanied by inflammation and ulceration of the glands of Peyer, and other characteristic phenomena, (*dothinenteria, typhoid affection;*) whilst in other countries, as in Great Britain, it exhibits itself more frequently by a distinct eruption, and absence of intestinal ulceration (*typhus*), and in certain localities, again, may assume an erysipelatous character, as in the adynamic fever, (*black tongue*), which in the year 1842 was observed epidemically in different parts of this country. The writer's opinion is affirmative; yet some pathologists regard them as distinct diseases, *ab origine*.]

2. Numerous and accurate observations have been made, particularly by Drs. Perceval, Cheyne, Grattan, and other Dublin physicians, Drs. Bateman, Tweedie, and others in London, and Andral, Chomel, and Louis, in France, confirming and extending those of Sydenham, on the more complicated forms of fever, in which the symptoms denoting or threatening local inflammation in the head, chest, or abdomen, combine themselves, either from the first, or at different periods during the disease, with those of the idiopathic fever; and it has been clearly shown that it is by no means exclusively with the inflammatory form of the general febrile symptoms—firm pulse, hot skin, &c.—that this combination may take place; but that, on the contrary, the danger in a majority of the worst cases of fever in this climate depends on a complication of local affections, with general symptoms, which, if standing alone, would as clearly demand stimulants.

The observation of such varieties in the general symptoms and in the local concomitants of fever is especially important when taken in connection with the varieties in the symptoms which, in the fatal cases, immediately precede death, the different *modes of fatal termination* to which different cases obviously tend, and the different kinds of practice which are, therefore, evidently demanded. When we see, for example, that some cases of fever are fatal within a few days of their commencement, with the pulse full and the skin hot almost to the moment of death, and headach and delirium, followed by stupor, as the most prominent symptoms; and that others are fatal only at the end of several weeks, the pulse being feeble, or very easily depressed, the skin cool or easily chilled, and the body wasted by inanition, or more quickly reduced by diarrhœa, for many days before death, but the head clear almost to the last; it becomes obvious that Dr. Cullen's memorable injunction, to form the indications on "the means of obviating the tendency to death in fever," must be followed by very different means. Perhaps the most systematic account of the different modes of fatal termination which are to be expected in fevers, and by the expectation of which the practice must be chiefly regulated, is to be found in the work of Hildebrand on Typhus.

3. The observations, begun by Sydenham and others of the older authors, on the comparative frequency and mortality of the different forms of fever at different ages, in different climates, different seasons, or in different epidemic visitations of the disease, have received many important additions.

The last-mentioned point is, perhaps, that on which it is the most important to have certain information. In the fevers of the hot climates, for example, it appears distinctly from numerous practical observations, that in some seasons the danger is chiefly from the rapid increase of symptoms denoting an inflammatory action at the brain and at the liver or stomach, headach, delirium, stupor, pain and tenderness at stomach, urgent vomiting, &c., and that these symptoms are safely and effectually met by full evacuations; but it seems equally certain that, on other occasions, and in the more malignant epidemics, the febrile depression is more formidable, the depleting practice less effectual, the danger of debility from it much greater, and stimulating remedies sometimes (though unfortunately seldom) obviously successful.

The present writer can say with confidence, from his own observation, that the fevers which were prevalent in Edinburgh from 1815 till 1820 were materially different in character from those which have prevailed since 1825; that at the former time the pulse generally preserved a greater degree of firmness throughout the disease; that when death occurred, it could be more distinctly ascribed to the inflammatory complications; that bloodletting was better borne, and seemed much more decidedly useful; and that the indications for the use of wine, and the benefit from it, were much less frequently seen. When the statements of Dr. Welsh on the fever of 1817-18 in Edinburgh are compared with those of other practical observers, either of former or later epidemics in Scotland, it will probably be admitted that the observation now made is in conformity with the experience of others. About the former period, several of the best observers, — Dr. Duncan in Edinburgh, Dr. Bateman in London, and many of the military and naval practitioners,—exerted themselves to show the safety and efficacy of bloodletting in fevers, even of the typhoid type; but in many of the fevers prevalent since that time, caution has appeared equally necessary in regard to bloodletting, and wine has seemed equally useful and important as in the days of Huxham or of Gilchrist. And it is only by such observations that we can be duly impressed with the importance of the practical cautions given by Sydenham, by Cullen, and others of the older authors, as to the importance of attention to *the nature of the prevailing epidemic*, in regulating our practice in fevers.

What has been said of the connection of fever with the local inflammations frequently attending it, may be applied likewise to the Contagious Exanthemata, in which there is a similar combination of general febrile symptoms, consequent on the introduction of a poison into the blood, with peculiar local inflammations chiefly of mucous membranes; but these are of a more definite character, both as to seat and duration, than in the former case. In these, likewise, a remarkable variety of epidemics, as well as of individual cases, has been repeatedly observed of late years; of which the peculiarly malignant or typhoid measles, prevalent in Edinburgh in 1807-8 and in 1815-16, were striking examples. The idea entertained by Dr. Watt and some others, of an increased mortality from measles compensating for the diminution of mortality in early life which had been effected by vaccination, seems to have been a hasty inference from the observation of such an unusually fatal epidemic, and has fortunately received no confirmation from subsequent experience.

The malignant Cholera, which has been the object of so much attention within these few years, has all the characters of a disease proceeding from a peculiar or specific poison, whatever the source of that poison may be. Many of its symptoms approach nearly to those of the congestive form of fever above mentioned; and the typhoid symptoms and strong tendency to stupor, observed very generally in this country in those who recovered from the stage of collapse, clearly indicate its analogy to the worst febrile epidemics.

It is obvious from what has been said, that much has been done in the last half century to increase the number and the precision of the data, by which we are habitually guided in the application to individual cases of this class of diseases, of remedies of known and acknowledged power, *e. g.* bloodletting, general or local, purgatives, nauseating medicines, counter-irritants, stimulants; and it were unreasonable to doubt that in this way the efficacy of medical treatment over these diseases, in the practice of intelligent and judicious men, has been gradually and considerably increased. We must ascribe much less to the peculiar efficacy of any new remedies recently introduced. The application of Cold in the early stage of Fever and of Scarlatina is one of those from which the most beneficial results have been anticipated, and the temporary efficacy of this remedy, and the safety of applying it during the stage of greatest vascular excitement, in the simpler or less complicated forms of these diseases, were ascertained by Currie and many others; but a careful observation of the "modes of fatal termination" of these diseases is sufficient to show that the cases to which this remedy can be safely and freely applied, are not, in general, those in which danger is chiefly to be apprehended; and it is probably to the conviction of this truth that we ought to attribute the gradual disuse of the most powerful method of applying cold in such diseases, the cold affusion.

The free use of saline medicines in fever has been lately recommended by Dr. Stevens and others, on the supposition that they have a peculiar or specific power of correcting the morbid state of the vital properties of the blood, which is indicated by its imperfect coagulation, and are therefore qualified to obviate the typhoid tendency in fevers; and it is certain that the indication which it is thus proposed to fulfil is one of real existence and importance, and that the effect of small quantities of saline matter in accelerating the coagulation of fresh-drawn blood, would seem to favour the idea of its power to correct that morbid condition. But it is a mistake to suppose that the mere reddening of venous blood by salts is an indication of any such change on the vital properties of the blood, as would be requisite to make their use effectual for the purpose in view; experience of the saline medicines in fever does not authorise our attributing to them any peculiar power over the typhoid symptoms; and although the saline injections into the veins have frequently had an extraordinary temporary exciting effect in the stage of depression or collapse of the malignant cholera, yet the very frequent accession of coma, after that copious admixture of saline matter with the blood, will hardly justify the hope of any improvement as to that most formidable part of the typhoid symptoms resulting from the saline treatment.

We must still admit that the only medicines to which we can confidently ascribe a peculiar or specific virtue of controlling the morbid actions which constitute fever are bark and arsenic, when used in the intervals of intermittents; and the improvement in the administration of the former medicine effected by the introduction of the Sulphate of Quinine into general practice by Pelletier

and other French pharmaceutical chemists, is one of the most important additions which chemistry has given to medicine during the period under review.

CHAPTER III.—*Recent additions to our knowledge of chronic diseases*—1. *Of organic diseases*—*Their diagnosis*—*Their arrangement and classification*—*Their connections with each other and with acute diseases*—*Their treatment*—2. *Of functional disorders*—*Their connections with one another*—*The general principles of their treatment*—*General reflections on the past history and future prospects of medicine.*

It will easily be understood from what has been already said, that some of the chief recent improvements in medical science will be found in the increased extent and precision of our information as to Organic Diseases, *i. e.* diseases dependent on permanent changes of structure in some of the organs. This department of medicine has likewise been studied with great care and minuteness by the French pathologists. It must be admitted that the diseases which are thus characterized are for the most part incurable; and that, most generally, it is only in so far as they are complicated, either with inflammation or with strictly functional disorders, that they admit of the application of any remedies of more than palliative operation; yet the knowledge of their existence is frequently of practical importance; and when the information which we acquire from studying their symptoms in the living body, and their appearance in the dead, can be connected with the investigation of their predisponent and exciting causes, and the mode of their formation, it may be usefully applied, even at present, and we may trust will hereafter become more extensively applicable, to the *prevention* of evils for which the past history of medicine gives us little reason to expect that any medical treatment will ever supply a remedy.

The most important additions made to our knowledge of this class of diseases may be mentioned under the following heads:—

1. The diagnosis of them, during life, has been greatly improved by comparison of symptoms, observed in many cases, with accurate investigation of the lesions discoverable on dissection. This, indeed, appears from what has been already said of the improved diagnosis of chronic inflammation and its effects, which, in many instances, are not to be distinguished during life, (otherwise than by their often abating, spontaneously or under remedies, more favourably,) from the more strictly organic diseases.

It is chiefly in the discrimination of chronic diseases of the thorax and abdomen, that the advantages of the methods lately brought into use may be observed. The observation of the functions which appear chiefly disordered is, certainly, in chronic as in acute cases, our first guide to the organ which may be judged to be affected; but this observation is sometimes deceptive, and often insufficient for such distinctions as may be confidently and usefully drawn. We now know that effusions, either into the cavity of the chest or into the air-passages, that morbid condensation or morbid rarefaction of the substance of the lungs, or the formation of cavities within them, all modify the sound emitted by the chest on percussion, or the resonance of the voice from it, or alter, or add to, the natural respiratory murmur, generally or locally; and so produce peculiar symptoms, which, when existing alone, may be recognised by most persons without much difficulty; and even when combined, as so frequently happens, with one another, still frequently enable us to judge of the nature of complex cases with a degree of precision formerly unattainable.

The existence of enlargement of the heart and of dilatation of the aorta, and of obstruction to the transmission of blood through the heart, is in almost all cases distinctly discoverable by manual examination, connected with a few facts easily ascertained, as to the sense of palpitation and the manner in which it is excited; in some cases, more specific information is obtained as to disease of the pericardium by percussion; and as to disease of the valves of the heart by the modifications of the natural sounds of the heart's action, perceived by auscultation; and the existence of aneurisms within the chest, otherwise imperceptible, may sometimes be ascertained in this way.

As an example of the increased precision of our knowledge of chronic diseases of the chest, we may instance the judgment which no careful observer will now hesitate to pronounce, on Dr. Cullen's definition of hydrothorax, comprising a number of symptoms which it is of great importance for the practitioner to observe, but none of which, singly or combined, do necessarily indicate that disease; and two of the most important of which, the starting from sleep with palpitation, and the sound of fluctuation in the chest, actually never attend the disease, unless it be complicated with others; while the symptoms most truly characteristic of the effusion into the chest, (the dull sound on percussion, and absence of respiratory murmur, altering their place on change of position,) are not mentioned in this definition at all.

It is true that much obscurity often attends the diagnosis of the more complex chronic diseases of the chest, even with all the aids that we now possess; and that to clear up this obscurity, in too many cases, would answer no practical purpose; but the statement that has been made of the improvements of diagnosis, as applicable to the simpler cases at least, since the time of Cullen, does not appear to be exaggerated.

It has been found that the existence of organic disease, giving an unnatural density to parts within the abdomen, may also be detected in some instances by aid of the sound emitted on percussion, (as practised by Piorry and others,) with more certainty than by the touch alone. Many organic changes of structure to which the different parts of the alimentary canal and the chylopoietic viscera in general are liable, have been carefully observed, and their symptoms (unfortunately some of them sympathetic and remarkably various) been recorded; and the discovery of the connection of organic disease of the kidneys with urine of low specific gravity and albuminous character, has enabled us to speak with confidence of the chief cause of derangement of the health in many cases which are otherwise ex-

tremely obscure. It is well observed by Andral, that organic diseases of the liver, when, as often happens, they are neither made known by enlargement of the organ, nor by jaundice, nor even by any obvious deficiency of bile in the fæces, are at present more obscure than those of any other important viscus. The organic diseases of the testes, the prostate gland, and the urethra in man, and those of the uterus and ovaria in women, have been subjected, of late years, to repeated and careful inquiry; the symptoms which may excite suspicion of them are known, and detection of them by examination is seldom a matter of much difficulty.

As examples of the increased precision given to our knowledge of the variety of organic diseases, we may mention the accurate descriptions of those of the eye by Ware, Travers, Lawrence, [Mackenzie,] and others in this country, as well as by many foreign authors; and, again, the minute discrimination of the diseases of the joints, as they originate in different textures, by Sir Benjamin Brodie; all which distinctions, in cases which are carefully traced from their commencement, may often be recognised.

2. Not only has much been done to enable us to pronounce, with more confidence than formerly, on the existence of organic changes of structure in various parts of the body, but the whole history of the changes which come under this description has been much elucidated by observation, both in the living and dead body.

Most of these depend on the deposition, and many ultimately on the ulceration, of adventitious or morbid matter of one kind or another, either substituted for or added to the original materials of the different textures; whether these are external and exposed to view, or internal, and to be recognised, partly by the functions which seem chiefly deranged, and partly by the modes of examination to which we have referred. From the time of Mr. Abernethy's Classification of Tumours, many minute descriptions of the great variety of these deposits have been attempted both in England and France, [and America,] to some of which we shall presently advert; but it is perhaps impossible to embrace all these varieties in any formal arrangement. Probably the most successful attempt of the kind is that now in progress by Dr. Carswell, which affords a good illustration both of the increased accuracy of our knowledge of morbid anatomy, and of the advantage which is taken of the arts of the draughtsman and engraver, to diffuse and perpetuate that knowledge.

We have already spoken of the important practical question frequently presenting itself, how far an inflammatory action produced by the usual causes of inflammation may be concerned in determining their formation, and how far they must be referred to mere "perversion of nutrition" from unexplained causes. This question frequently occurs, and may be answered nearly in the same terms as to every variety of morbid structure, from the simplest morbid cysts or hydatids up to bony concretions, and scirrhous or cancerous tumours; and the writings of Broussais, Laennec, and Andral, show the importance attached to it by modern French pathologists. All that can be said in regard to it in general terms is this, that effusions which are simply the effects of chronic inflammation, may produce, probably in any part of the body, effects and symptoms almost exactly similar to those which result from the deposition of morbid matter, and the growth of adventitious textures; and that effusions, in the first instance produced by inflammation, may probably be gradually converted in different cases into any such morbid growths; but it is obvious that some additional condition of the morbid state must exist in every case where such conversion takes place; and experience instructs us, that when that unknown condition exists, all sorts of morbid degenerations of structure may be gradually effected, without either the application of the usual causes of inflammation, or the appearance of its usual symptoms.

There are two general grounds of distinction among adventitious textures or morbid growths, which are of obvious and practical importance, and have therefore fixed the attention of many pathologists, but which are often not easily recognised in individual cases, and are evidently not in all cases strictly observed by nature.

The first is the distinction of the diseases properly termed *malignant* from those which either become inert and stationary, or tend, however slowly, to a spontaneous favourable termination. When a decidedly scirrhous tumour has formed in any part of the body, when a deposition of the nature of the encephaloid matter or medullary sarcoma has taken place, or when a sore has assumed the character of hospital gangrene, nothing but continually extending ulceration and ultimately exhausting constitutional disturbance can be expected; whereas the more common tumours, encysted or sarcomatous, on the surface of the body, polypi, of the common kind, on mucous membranes, fibro-cartilaginous tumours of internal parts, *e. g.* of the uterus, even the most common morbid depositions on the coats of the arteries, or valves of the heart, or in the substance of the liver or kidneys, although they may interfere with important functions, and so prove dangerous, are not necessarily destined in themselves to such unfavourable progress.

The other distinction is one which points to the same conclusion, both as to prognosis and practice, but by no means coincides with the former, between those organic diseases which are *constitutional*, and those which are strictly *local*. We apply the former term to those formations which are known by experience to be found very generally in different parts of the body at once, and particularly in internal parts at the same time as in external; the matter composing which has been found also, by Langstaff, Velpeau, and many others, in the blood within the vessels, chiefly in the veins leading from parts where extensive depositions have been going on, and of which it has been frequently observed that the removal of a limb, seriously affected by them, has been quickly followed by a rapid deposition of the same kind in internal parts. This character is so far applicable to the scrofulous tubercles, the whole history of which has been so fully elucidated by Stark, by Baron, Lloyd, [Gulliver,] and others in this country, and by Bayle, Laennec, Andral, Denis, Lombard, and others in France; but the latter particu-

lars above stated have been found to apply more uniformly to two other kinds of morbid or adventitious structure, accurately described and distinguished only within the present century, and which are formed in general more rapidly than the scrofulous tubercles, viz. the medullary sarcoma, encephaloid disease, or fungus hæmatodes, and the melanosis; the first of which varies considerably in different instances, and has therefore acquired the above and various other names from Abernethy, Hey, Wardrop, Burns, Farre, Monro, Tertius, and others who have described it within the last thirty years, in this country; while the latter is so very peculiar, that since it was described by Breschet, Laennec, and Béclard in France, and by Fawdington, Cullen and Carswell, and others in this country, there has been no difficulty in restricting the term to the proper description of cases.

In regard to these diseases, although we can point out several circumstances which seem to predispose to them, yet it seems obvious, from what has been very frequently observed in regard to them, that the circumstance which gives the strongest predisposition to the formation of any one of them in any part of the body, is the previous existence of the same morbid texture in another part, and that the chief cause of their formation is a constitutional peculiarity rather than a local irritation.

Many other kinds of morbid growths (particularly those which differ the least from the sound textures of the human body) have no such tendency to occur simultaneously or in succession in different parts of the body, and may therefore be more safely and advantageously removed in many instances where they have formed in external parts. The tendency to reproduction after the removal of an affected part is less uniform in the case of the scrofulous tubercles than of the other diseases now mentioned; but the great tendency to repeated deposition in internal parts is what, in fact, gives the great fatality to scrofulous disease, for individual tubercles are not uniformly destined to extension, or even to ulceration, and the epithet of malignant is, therefore, not strictly applicable to them. On the other hand, the tendency to reproduction after removal is very strongly marked in the true scirrhus after it has subsisted for some time in any part of the body, and particularly after any of the lymphatic glands have been affected by it; so that we must always expect that malignant form of disease, however strictly local in the first instance, to become constitutional shortly after it has discovered itself.

The facts stated as characterizing the constitutional organic diseases seem to leave little room for doubt that they essentially depend on alterations of the constituents and vital properties of the blood; and that the peculiar matter of which they consist is, at least to a certain degree, elaborated in the interior of the vessels, and forms part of the circulating fluid, if not from the commencement, at least in the progress of the disease. This principle is evidently illustrated by what has been already stated as to the evidence of purulent matter circulating in the blood in cases of inflamed veins, or of extensive suppuration of other parts. And the dependence of such local depositions on a morbid state of the blood is farther illustrated by the facts observed in regard to the singular disease lately called Purpura, but long since accurately described by Dr. Duncan, sen., under the more characteristic term hæmorrhœa petechialis; some cases of which, indeed, approach very nearly to those cases of melanosis where the morbid matter is most generally deposited.

The phenomena of Scurvy, strictly analogous to those of purpura, afford the only example yet known of an alteration of the vital properties of the blood, the essential cause and auxiliary predisponents of which are known, and the means of correcting which are equally simple and certain. The peculiar efficacy of the citric acid in particular, according to the statements of Sir G. Blane, seems well ascertained. But the absolute inefficacy of the same treatment in cases of purpura sufficiently indicates that similar conditions of the blood may result from various causes. Numerous recent observations on purpura have shown that it is often complicated with inflammatory diseases, and then may admit of relief from antiphlogistic treatment,—a conclusion quite in accordance with what has been stated as to other diseases connected with a morbid condition of the blood.

There is yet another description of organic disease in which it is pretty certain that the morbid product is the result of vital changes which take place among the constituents of the blood in the interior of the vessels, viz. some of the fungous growths or vegetations which are occasionally found attached to the valves of the heart. From several cases, which he has himself seen, the present writer has no hesitation in agreeing to the doctrine of Laennec, that certain of those substances are not growths from the lining membrane of the heart, but coagula of blood, gradually forming and attaching themselves, and acquiring a peculiar organization.

There are many cases of disease in which organic lesions of the solids composing the animal frame are effected without the deposition of new or adventitious matter,—cases of atrophy, or hypertrophy, or alteration of the form and position of parts, leading in many cases to derangement of functions, or giving still more unequivocal indications of their existence, by alteration of the outward appearance of the body. These cases have likewise attracted the particular attention of pathologists; and what is most important in this department of pathology is, the distinct apprehension of the manner in which (consistently with known laws of the animal economy) many of these alterations of structure are effected, in consequence either of inflammations and effusions, or of other organic diseases, or even functional disorders, previously existing. Thus, atrophy of parts may often be traced to their disuse, and hypertrophy to their excessive use, in consequence of other disease, and both illustrate the dependence of nutrition on local changes occurring at the extremities of the arteries. The emphysema of the lungs already mentioned, and the enlargement of the bronchi, are naturally consequent on many cases of bronchitis and effusion into the air-passages, but constitute, when effected, important organic diseases in themselves. In like manner the common case either of dilatation or hypertro-

phy of the heart, so fully investigated by Corvisart, Laennec, Bouillaud, Andral, Baillie, Burns, Farre, Hope, and many others, is very seldom a diseased state in itself, but is the natural consequence, produced in a healthy part by obstruction to the exercise of its function, of disease (inflammatory or organic) of one part or other of the membrane lining the inside of the heart and aorta. So, also, the expansion of the cranium and unfolding of the convolutions of the brain in the chronic hydrocephalus is a consequence of the gradually increasing effusion of serum in its interior; the gradual conversion of the kidney into a cluster of cavities, communicating with each other and filled with fluid, is the natural effect of obstruction of the ureter, causing enlargement of the calices, and compression and absorption of the glandular substance; and the great alterations in the form and other qualities of bones, both in the mollities ossium and in the spina ventosa, appear to be, frequently at least, consequent on morbid growths from their internal or medullary membrane.

3. Not only the history of most of the organic diseases has been greatly elucidated, but the more general consequences which they produce, the predisposition which they naturally give to other diseases, and therefore their connection with inflammations, with functional disorders, and with one another, have in many instances been made out; and in a practical view, this is one of the most important inquiries concerning these diseases in which pathologists have lately been engaged.

Thus it is now well understood that the very common disease of the arteries, which begins by deposition of lymph on their inner membrane, and generally goes on to ulceration and irregular bony depositions there, is naturally the great predisposing cause of many and very different diseases,—that in the trunk and extremities it often leads to aneurism, and in the extremities it is often connected with gangrenous inflammation; that in the brain it often leads to rupture of vessels and apoplexy or palsy; that in the neighbourhood of the heart, and especially when the morbid deposits extend to the valves of the heart, it obstructs the circulation there, and leads to dilatation and hypertrophy, to palpitations, to fits of syncope, sometimes to angina pectoris; that the obstruction on the left side of the heart gives a great predisposition both to peripneumony and to rupture of blood-vessels, producing hæmoptysis and apoplexy of the lungs, and seldom fails, sooner or later, to induce chronic bronchitis, with which, in certain constitutions, fits of spasmodic asthma are combined;—farther, that this as well as other causes of obstruction to the free flow of blood through the heart and lungs, producing habitual dyspnœa, leads naturally to congestion in the great veins, and thereby to enlargement of the liver; and that it is chiefly after the disease of the heart and arteries has already become complicated with disease of the lungs or liver, that dropsy, more or less general, is so apt to supervene. In like manner we can easily trace the connection, in many cases, of bronchitis and asthma with emphysema of the lungs and consequent habitual dyspnœa, and then with enlargement of the liver and dropsy;* or that of obstructed liver, first with dyspeptic symptoms, and then either with ascites, or with diarrhœa, dysentery, melæna, or hæmatemesis.

But in all these cases it is to be observed, that the pre-existing organic disease acts only as a great and permanent *predisposing* cause of the various derangements, functional or organic, which thus combine themselves with it. When existing alone, any one of these organic diseases may exist, at least in some individuals, for a length of time without causing any very urgent symptoms; and the occurrence of these complications may very often be ascribed also, in part, to the action of *exciting* causes of disease,—cold, intemperance, exertion, &c., and to inflammatory attacks connected with these. In fact it is chiefly by warning us of the specific dangers to be expected from such exciting causes, and of the importance both of avoiding them, and of watching for any fresh accessions of inflammatory symptoms, and using depleting remedies as early as possible to subdue them when they appear, that the knowledge of the usual successions of such diseases is useful.

4. The precision which is thus given to our views of the effects to be expected either from bloodletting or other evacuations in the varying circumstances of organic diseases, of the time when they should be used, the objects to be gained by them, and the circumstances in which no advantage can be anticipated from them, is certainly the principal practical improvement which has resulted from our extended acquaintance with the pathology of such diseases. In cases of dropsy, additional evacuant remedies, of the class of diuretics, particularly the digitalis and the pyrola, have been introduced within the last half century, and from the former, at least in many cases, very striking effects have been obtained.

Many hopes have been entertained, at different times, of the discovery of medicines possessed of a true and specific deobstruent or alterative power; but it must be admitted that these have been generally disappointed. At the same time it is probably going too far to say, in the words of Sir B. Brodie, that when any texture of the body has been altered from its natural condition by disease, that natural condition is never restored. We undoubtedly meet with cases where unexpected recovery from what appear to be the symptoms of unequivocal, although probably incipient organic disease of some of the internal viscera, takes place under the judicious use of mercury, or of the sulphureous and saline mineral waters, or of iodine; and we cannot regard the recommendations of these remedies and the rules for their administration, contained in many recent works, as practically unimportant, nor doubt of the introduction of the last-named medicine, by Dr. Coindet, having been a real addition to the resources of medicine. But it must be admitted that the virtues of all these remedies have been much exaggerated by most of those who have undertaken

* When disease of the liver has been found connected with organic or habitual disease within the chest, it has been often supposed, in this country, that the former has been the primary disease; but the present writer is quite satisfied that the statement of Andral, as to the pre-existence of the thoracic disease, in most such cases, and the mode of production of the liver disease, is very generally correct.

to recommend them; that in a great majority of cases they are obviously quite inadequate to the object to be accomplished; that when they have succeeded, the morbid structures which existed have probably approached more nearly than is usual to the effects of simple chronic inflammation, and been obviated in part by the repeated although cautious use of the ordinary remedies for inflammation; that some of these remedies have injurious effects on the body which are often just objects of apprehension, (of which mercury in scrofulous habits is the most important example;) and that, in the present state of our knowledge, the discretion of the medical practitioner is very often most usefully exercised in withholding any such remedies, and confining himself to palliative treatment only, in cases which are truly beyond the reach of any alterative or deobstruent medicines yet known.

Important practical observations have been made by Sir Benjamin Brodie and others, on the diagnoses of those organic diseases of more external parts, especially of bones and cartilages, in which counter-irritation has proved most successful; but these are perhaps rather to be regarded as cases of chronic inflammation and its consequences than of strictly "perverted nutrition."

This is not the proper place to dwell on the surgical treatment of those organic alterations of texture which admit of relief from such means; but the great improvements in the treatment of aneurisms, of strictures of the urethra, of polypi of the uterus, and the use of various escharotics to destroy the surface of intractable ulcerations, as in the case of the arsenical solution applied to the hospital gangrene, of the nitric acid to phagedenic venereal sores, of the lunar caustic to the more common syphilitic ulcers,—even of different escharotics to incipient ulcerations of the os uteri, are all examples of the successful application of expedients of this kind, the proper use of which was formerly imperfectly understood.

The last class of diseases which may be noticed in this sketch of modern improvement in medicine is that where the functions of different organs only are disordered, without either inflammation or fever, or organic alteration of structure; and although this class is very numerous, and demands much of the care of medical practitioners, it need occupy only a small share of our attention at present; because the disorders which it comprehends are less accurately defined, their history is more various, the effects of remedies upon them are more uncertain, and the observation of their effects is liable to more fallacies; so that the information which we can acquire in regard to them cannot have the same character of precision as that which we possess in regard to those diseases of which the symptoms and anatomical characters are better marked and more uniform. In some instances, however, merely functional diseases have been described and distinguished of late years with a degree of precision formerly unknown, and practically important.

The greater number of the functional derangements to which we here allude are included under the two heads of disorders of the digestive organs, and disorders of the nervous system; but some cases of dropsies unconnected with perceptible organic disease, some cases of derangement of secretion unconnected with digestion, and many chronic affections of the bronchi, and of the surface of the body, may be held to belong to this class, as being derangements of secretion rather than either inflammatory or organic diseases.

Now it may be remarked of these diseases, that perhaps the most important general principle lately ascertained in regard to them, is that of the sympathetic connection existing among them, and, therefore, the possibility of effectually correcting one disorder of this class by applying remedies, apparently, to another. Thus the dependence of many disorders of the nervous system on imperfect digestion, and derangements of the bowels, not as the sole, but in many instances as one of the conditions of their existence, seems well established; and it is generally believed that the same principle extends to disorders of distant secretions, (*e. g.* to that disorder of the secretion of urine on which the formation of calculi depends,) and to many chronic cutaneous diseases. The Treatise on Purgative Medicines, by Dr. Hamilton, senior, and the Essay on the Constitutional Origin of Local Diseases, by Mr. Abernethy, have strongly impressed the practitioners of this country with the importance of careful attention to the state of the primæ viæ in many cases, where the organs chiefly affected appear to be distant from that source of irritation. It may be doubted whether the remedies which have appeared so useful in the hands of these practitioners have always acted merely in the way they supposed; it may be doubted, for example, whether the purgatives used by Dr. Hamilton in chorea, in hysteria, or in threatening of hydrocephalus, have acted merely as evacuants of irritating matters from the bowels, or chiefly as *derivants* from the brain and spinal cord; it may be doubted whether the small doses of mercury prescribed by Mr. Abernethy in cutaneous ulcerations and other disorders of external parts, have acted merely on the stomach and bowels, or chiefly as alteratives on the whole system; and it is certain that in different states of the primæ viæ, different plans of treatment from those chiefly insisted on by those authors, will be found most effectual. Still, the general principle of correcting the functional disorders of other parts of the body, by the diet, regimen, and medicines, which most effectually improve and preserve the state of the digestive organs, is generally acknowledged as highly useful and important.

Another important observation lately inculcated by several practical authors, is that of the ready transition of functional disorder, when neglected or irritated, into inflammation, generally of the more chronic character, and the importance, therefore, of the antiphlogistic treatment in a number of cases, which, judging at least by their first symptoms, might be supposed to present no indications for loss of blood, or even for low diet. The writings of Dr. Cheyne and other recent authors on hydrocephalus, of Dr. Parry, of Dr. Wilson Philip on dyspepsia, and of Broussais and his followers, afford many illustrations of this observation; and as usual, when a principle previously neglected has been illustrated, this kind of practice has been carried too far by the last mentioned authors.

The attention of the profession has been properly fixed by several practical authors of late years, on certain forms of disorder of the nervous system, which were not formerly distinguished with sufficient accuracy, and which demand the more attention as they often closely resemble the inflammatory diseases of the nervous system, although the most successful treatment of them is very different from that which true inflammations require. The Delirium Tremens, so accurately described by Pearson, Sutton, Armstrong, &c.,—and the power of opium, [and even of large quantities of alcoholic liquors,] under proper management, in controlling it, is the most striking example. The accurate investigation of cases of spectral illusions and somnambulism or reverie, is likewise of modern date. We may mention, also, the careful diagnosis of neuralgic pains, and the use of some remedies, of the class commonly called tonics, such as the carbonate of iron, recommended by Mr. Hutchinson and others, in their treatment; the dependence of many such disorders on morbid action at the roots of the sensitive nerves of the parts apparently affected, (which seems to be ascertained by the observations of different authors on what has been termed Spinal Irritation); and more especially the important observations of Dr. Marshall Hall, Mr. Travers, and others, on a state of excitement, resembling inflammatory fever, in certain constitutions, to which they have given the name of Reaction after the Loss of Blood; and again those of Dr. Abercrombie, Dr. Gooch, and others, on the symptoms closely resembling hydrocephalus in children, which are consequent on long-continued diarrhœa, or other evacuations, and abate under the use of stimuli.

It were tedious to enumerate the different individual medicines which have recently been proposed and approved by many practitioners in strictly functional diseases; but it seems important to remark, that the advantages to be derived in many chronic disorders unconnected with organic disease, from change of scene or of climate, from residence in the country, from the vegetable alteratives, as they have been called, such as the sarsaparilla, and from the saline, sulphureous, and chalybeate mineral waters, have been more fully appreciated of late years than formerly; and there is good reason for thinking that such remedies and regimen, acting primarily, or at least most obviously, on the organs of digestion, may often be effectual, not merely in correcting functional derangements, but in so restoring the natural vital properties of the blood, as to obviate the predisposition to organic disease, which might otherwise be gradually formed.

On the whole, in taking a general view of the different stages of improvement of medical science, it may be stated that the ancient physicians, entertaining the most inaccurate notions as to the functions of the body in the sound state, and as to the essential nature of diseases, were yet enabled, by empirical observation, to acquire a surprising extent of accurate information, as to the external causes and natural progress of diseases, and as to the power of remedies over their most formidable symptoms. In more modern times physiologists have acquired a general knowledge of the nature of all those functions in which the visible movements of the body are chiefly concerned, and so far contributed to the elucidation of many diseases; while the distinctions of the different diseased states, so far as they appear during life, have been ably arranged and classified in the systems of Nosology; the application of remedies to them has been reduced to a more regular system than formerly; and the lists of really efficient remedies have been gradually curtailed, and their properties more accurately determined.

The great improvement of late years has been chiefly owing to the more diligent cultivation of morbid anatomy, whereby the localities, the varieties, and the natural effects (whether perceptible during life or after death,) of almost all the diseased states of the body have been more accurately ascertained. At the same time, by the improvements in physiology, the immediate causes of the fatal termination of diseases have been in most cases explained; and thus the immediate objects to be attained by medical practice have been more clearly defined, and additional precision given to the administration of remedies, the powers of which had been already established.

In looking forward to the farther improvement of the art, we can hardly expect that the most numerous class of remedies, — those which produce sensible effects on the body, — can either be made to exert more power, or be directed with much more accuracy towards the objects which they are capable of accomplishing, than they may be at present, by well-informed and judicious practitioners. Our hopes of the increasing usefulness and efficacy of our art must depend, partly on the improvement of medical education, and the more uniform diffusion, through the members of the profession, of the knowledge which we already possess; but partly, also, on the progress which may yet be expected in two lines of inquiry, in which our success has been as yet only partial,—*first*, in the discovery of Specifics, which may counteract the different diseased actions of which the body is susceptible, as effectually as the cinchona counteracts the intermittent fever, citric acid the scurvy, or vaccination the small-pox;* and, *secondly*, in the investigation of the Causes of disease, whether external or internal; *i. e.* of the conditions under which, either the vital actions of the solids, or the vital properties of the fluids of the body, become liable to deviations from their natural state.

That the vices, and follies, and necessities of mankind will, throughout all generations, be a fruitful source of disease, as well as of other misfortunes, is as certain as that an origin of moral evil has, for mysterious purposes, been implanted in every human breast; but there is nothing irrational or Utopian, or inconsistent with the past progress of human knowledge, in the hope that

---

* [It is to be regretted, that one so philosophic in his general views as Professor Alison should encourage the search after "specifics," which has been the occasion of more empiricism, in and out of the profession, than any other fallacy. Not one of the agents, which he has named, is entitled to the epithet. They are all prophylactics, whose action is explicable on general principles, and none of them are capable of neutralizing or relieving the very complaints for the prevention of which they are employed. The writer is not aware of a single specific in the lists of the materia medica.]

our knowledge of the causes and intimate nature of diseases may be gradually so extended, and our powers of resisting them so increased and defined, that human judgment and foresight may ultimately be found adequate either to prevent or relieve all the sufferings, which we now regard as necessarily attendant on our physical constitution; and therefore, the defect of those moral qualities, rather than ignorance of the laws of nature, be justly chargeable for all, as it already is for many, of those physical evils which it is the office of the physician to alleviate.

W. P. Alison.

MEDICINE, PRACTICAL, PRINCIPLES OF.—In the article Disease was necessarily presented to the reader a long catalogue of evils, which, however, man has not been left unprovided with the means of meeting or of combating; some of them he has been enabled to mitigate, and others have quite disappeared before his increasing knowledge and skill. In the same manner as beasts of prey and venomous and offensive reptiles lose their ferocity, or recede in all parts of the earth, and finally disappear, before the advancing civilization of mankind, so, also, it would seem, do the diseases which prey upon health and life become modified by the resources of man's ingenuity, or disappear before his discoveries and growing wisdom; and when philosophers perplex themselves concerning the origin of evil, they little suspect how many of the physical as well as moral ills of humanity are destined to disappear before the sagacity, the research, and the enlarged virtue of the species. The great kingdoms of nature have each already and amply contributed to reward human industry by remedies for the maladies of men; placing within man's power various substances which taken in certain quantities, or externally applied, produce beneficial effects on the frame when it is labouring under disease; that is to say, when its functions are disordered, or the structure of its parts is changed or impaired. Experiencing the effects, also, man has learned how to avoid many of the causes of disease. His reason to a great extent protects him; and would do so more effectually but for the force of habits formed before his reason acquires strength. By regulating the impressions made on the body and mind by some of the actual agents of disease, he has even converted them into occasional remedies; and, the practice of medicine becoming more comprehensive in its scope, and no longer confined to the administration of drugs or to the mere *cure* of maladies, has so far advanced as to include the means of preserving health unbroken in a great variety of circumstances, by which the mind and body are liable to be temporarily affected in the course of life.

These agents of disease have already been spoken of, as being external to the body or inherent in it: the air which surrounds it; the food which supports it; the exercise which promotes all its actions; the sleep which, after labour, refreshes it; the mind which governs and directs its voluntary actions and ennobles it; and all the inherited or congenital peculiarities to which it is liable, as well as all the accidents to which it is exposed in its progress from the helplessness of infancy to the second helplessness of old age.

When by the undue impression of any of these agents their morbid effects are produced, such effects consist of disorder in some of the corporeal actions, of which the secondary results have been pointed out as very various. If there is, first, some increase or some decrease of the energy of the nervous or of the vascular system, exhibited in one function, in more than one, or in all, there follow changes in the structural condition of the parts affected; whilst new formations seem produced by peculiar modifications of action, distinct from mere depression or augmentation of vital power. Certain laws of sympathy, of relation, and of conversion, have also been detected, which were comprehended in our general notice of disease; and by reasoning from the evident object of some morbid actions, an attempt was made (professing, certainly, little novelty) to establish the probable final cause of all.

If any endeavour to attain to general principles in medicine be thought worthy of encouragement, they must be sought, it appears to us, by pursuing the route thus marked out; by a review of the causes of disease, and of the forms which it assumes; of the results to which it leads, and of the general objects to which it tends. It is agreeable to believe that medicine is now cultivated by many labourers in a spirit so philosophical, that the young student who falls into the vulgar error of considering such a general view superfluous, may confidently be told that he will live long enough to see and to regret his mistake.

Before the forms and products of disease had been so minutely investigated as to admit of being detailed with any approach to exactness, the ancients were led, by the simple observation of the *causes* of disease, to adopt natural measures for restoring the equilibrium of a function disturbed. If a man became ill from exposure to a hot sun, he was cured by a cool regimen; and if from exposure to cold, a return to health was promoted by warmth, and sometimes by mere insolation. If too much food disordered him, he was relieved by abstinence; if too much exercise or labour had exhausted him, he was renovated by rest. Thus *contraria contrariis medenter* became one of the first maxims, or one of the first general *principles* in medicine. As knowledge advances, the general principles of treatment acquire a wider and a firmer basis; but this first principle, to which the ancients in their regulation both of treatment and regimen paid especial regard, has in some periods of medical history been departed from with disadvantage, and sometimes, and even recently, been utterly denied. The wise physicians of Greece saw nothing unreasonable in the belief that when the system was disturbed by a burning fever, the body was struggling to produce coolness; and when they beheld the frame shaken with a chilling ague, they concluded that an effort was making for that restoration of bodily warmth which they found to follow the cold fit: nor, probably, was their conclusion incorrect. Without neglecting these observations, the modern physician has much more to do. He endeavours to ascertain in what consist the first movements of nervous or vascular disorder, and in any disease presented to him, what actual change is already produced, and what further is threatened; so that his

measures may be properly directed, and with a promptness proportioned to the occasion; for he has not only to remove effects obviously induced and existing, but to check, suspend, and stop the less palpable actions out of which the structural mischief grows.

He knows that there is in many or in all functional disorders, and even in some which have gone on to the production of structural change, a tendency to salutary terminations. In the paroxysm of an intermittent, he can admit that the successive stages seem intended to effect the quiescence in which they terminate. Deep-seated abscesses, for instance in so large and important a viscus as the liver, show in their progress a tendency to seek or form communications by which the purulent collection may be carried away with safety. Almost all, perhaps all, the irritations of phthisis are the concomitants of an effort, always going on, for the riddance of the lungs from them; and the most deplorable changes in the course of schirrhous affections appear to be but the attempts of nature to break up or to separate from the body a portion so peculiarly diseased that its continued attachment to the system is inconsistent with the continuance of life. Admitting that these are the best means of relief which the laws of disease allow, and seeing, in too many melancholy examples, the inefficiency of the laws to the salutary end proposed, he cannot but draw the conclusion that *art* was intended to step in and supply what is wanting; and that it may often direct the actions thus originated, and sometimes most beneficially counteract them by others artificially excited. To know when to do this is an essential part of the wisdom of practical medicine, and a knowledge of the means of doing it is another of equal importance.

As a general rule it may be stated, (and the highest authorities might, if necessary, be quoted for it in every age of medicine,*) that wherever it can be safely done, the natural tendency to cure, supposing it to be evident, is to be followed. In very slight disorders no benefit arises from interference. A slight cold, or a slight diarrhœa, for example, will cure itself by the discharge which constitutes one of the first of the effects of the disorder. A slight hemorrhage, or a slight external inflammation, may also be left to itself; but for a more violent or continued hemorrhage, although its object be apparent and salutary, we must substitute means which are capable of giving equal relief, and are at the same time more under our control. A more severe inflammation, also, or even the slightest, if seated in a part not exposed to sight, can seldom or never be permitted to proceed uncontrolled; because inflammation seldom terminates without some product which may excite secondary inconvenience,—in other words, seldom terminates simply in what is called resolution, but either, when continuing, or when it attains a certain vehemence, ends, by a necessity arising from the laws of disease, in copious effusion, or in suppuration, or in the thickening or other alteration of parts, or the agglutination of opposite surfaces, or in ulceration, or mortification; the inconvenience or the danger of which effects, in the head, the chest, the abdomen, or the articulations and extremities, are such that art must be vigorously employed to arrest the progress of the first functional disorder, and prevent the advance to those new formations or structural changes which, albeit they are natural methods of cure, are methods inconvenient and incligible, or unsafe.

But it often happens that in the functional disorder, the disordered action is too violent, and will not be altogether suppressed: in these cases our efforts are limited to its moderation, and to conducting it to the least dangerous or least inconvenient termination that circumstances will permit. If effusions or suppuration cannot be prevented, their extent may be limited, or their escape facilitated; and if structural change cannot be altogether prevented, means may be found of saving a considerable portion of the suffering organ, so that its natural function may remain but slightly impaired.

When medical aid is sought for at a period too late to secure these advantages, and morbid actions have passed, unrestrained, into their ordinary effects on structure, medicine yet has its principles and resources. Circumstances have changed, and measures must be adapted to them. If effusion has taken place, as in various forms of dropsy, its absorption or its removal may be effected; if suppuration, its discharge, and sometimes its absorption; if structural change, its gradual repair or its removal. The resources are not always efficacious, but they always deserve a trial. Even when promising to be most successful, the frame is irritated by the presence and persistence of the disease, the strength of the body is reduced, and life is endangered. This irritation must, if possible, be allayed, the debility guarded against or removed, the danger to life averted. Whilst these indications are pursued, some new disease may be excited, or some of the *conversions* of which we have spoken (see Disease) may take place. The supervention of a new disease,—for instance, of pleuritis or phthisis,—always demands prompt attention; the conversion of the original disease into another is occasionally salutary; that is to say, when the new disease is less dangerous than the old, and entirely takes the place of it, as in the case of an affection of the skin supervening on disease of some internal organ. It is a very common object of art to produce this kind of conversion. Even a febrile disorder of the constitution has sometimes been considered capable of producing curative effects: Celsus enumerates among the accidental circumstances which cure the sacer ignis, *a day's fever;* "medicamentum ejus fortuitum est, uno die febris, quæ humorem noxium absumat;" (lib. v. cap. 28, s. 4,) thus adding the theory of the cure also. The authority of Hippocrates may be quoted to support a similar fact concerning convulsions dispersed by fever; and even epilepsy removed by the supervention of an intermittent; and Bartholinus and Salmuth are quoted by Hoffmann to the same effect. Hoffmann adds that he has often observed the convulsions produced by worms put an end to when a febrile action had destroyed the worms; considering the attendant fever as a salutary process set up to rid the body of the worms, effecting its pur

* Medicinæ leges naturæ legibus debent esse consentaneæ. Felix medicatio cui adjutrix natura succurrit, irrita vero quæ repugnante natura tentatur. *Fernelius*, in præfat. lib. i. See also *Hoffmann*, vol. iii. s. 2.

pose either by heat or by producing acrid bile.* Even chronic glandular disorders, which are perhaps generally exasperated by any febrile disorder, sometimes have disappeared, and old enlargements of the glands have seemed to be removed by an absorption induced by the fever attendant on measles.†

In all these instances, if we admit the facts without cavil, and in any other instances in which it may be thought salutary to excite any degree of fever, it can only be understood that certain circumstances accompanying the febrile state, certain conditions of the extreme vessels and nerves, are the causes of any benefit that is obtained. It must generally be more desirable to induce the same condition, if practicable, by other means,—by medicines which can affect the capillaries or the ultimate nervous actions without producing a concomitant fever; and this, we shall see, is another principle of practical medicine. By some of the older physicians, as by Van Helmont and Campanella, the disposition to regard fever as always a curative effort led to the mischievous doctrine that by all means the fever should be increased by calefacients and tonics. (See *Baglivi*, De Praxi Medica. lib. i. cap. xii. sect. 2.) This is one among many instances in which a correct principle has been hurtfully perverted; and the remains of this prejudice only disappeared in the memory of practitioners yet living.

If medicine could be so directed as to reach the first link in the chain of diseased effects, deep-seated and often hardly discernible, in the nervous and vascular systems, and to which the term *proximate cause* has often been applied, the treatment of mere symptoms would become but a small part of our duty. It is to this point that the efforts of enlightened medicine constantly tend. Whilst we try to relieve pain, we carefully seek for the diseased action of which it is a symptom; and, not content to allay the pain by destroying acuteness of sensation, seek to remove the diseased action, that a permanent cure may be effected. If we desire to suppress the immoderate evacuations of diarrhœa, we carefully consider what particular state of the intestinal canal occasions the disorder; and in such a case inconsiderate and empirical practice, never successful except by chance, may even be fatal. To attempt to remove the effusions attendant on chronic pleuritis or peritonitis, without regarding the continuance of the inflammatory disease, or to attempt to counteract the prostration of strength in a fever by other means than removing the febrile state, would be so exclusively to attend to mere symptoms, as to follow methods of treatment most inefficient and unsuccessful.

Yet it arises from the defective state of our pathology, combined with our anxiety, and even with our duty, to relieve the afflictions of the sick, that we are often glad to treat symptoms only; and sometimes it would appear, that when prominent symptoms are removed, the disease is at an end. As we can generally see and act upon the symptoms, although we are oftentimes unable to penetrate to the primary disordered actions, it happily follows that the limitation of our knowledge concerning the causes of disease does not determine the limits of our practical power, or always produce uncertainty or inconvenience. To the philosophical inquirer, however, it will always be unsatisfactory to be unable to account for some of the principal achievements of medicine; as the cure of an intermittent by bark, of syphilis by mercury, and of scabies by sulphur. In each of these cases the curative means are employed with singular confidence, and with general success; in each we see the grounds of hope that there are, even now, undiscovered remedies of equal efficacy in other maladies; yet, in each case, to speak candidly, it would be presumption to attempt an explanation of the mode in which the methods employed produce their marked and salutary effects.

To meet the complications of disease, the principles of treatment must often be equally complicated: two or more simple principles being not only simultaneously acted upon, but respectively modified by the existing circumstances of morbid complication. Chronic inflammation may exist with effusion, and both with debility; and although the principal indication or principle to be followed is in such a case to put an end to the inflammation, respect must be had to the existing debility, and relief from the mere effusion must neither always be postponed until the difficulty of acting on first indications is overcome, nor attempted without regard to the original cause or to the actual strength of the patient. There may be unequal growth, redundancy, or hypertrophy, in one or more portions of the frame, deficiency in others. General plethora may be combined with general debility. In these and numerous other complications, the principles of cure, being two-fold or three-fold, demand more from the practitioner than lectures on books can inculcate; a discriminating wisdom which must partly depend on his organization, and partly on his attention to the instructive examples afforded by daily practice.

Structural change is always preceded by disordered function, and the principles of treatment which are the ordinary guides of practice have reference to the means of restoring functional regularity. Disordered function consists, we have said, (Art. Disease,) of, 1, vascular disturbance or irregularity, producing local or general excess or defect of sanguineous supply; 2, nervous disturbance or irregularity, producing local or general excess or defect of nervous energy; 3, of combinations of these disturbances, producing various affections of nutrition, secretion, absorption, evacuation, muscular motion, or the sensorial offices, or the intelligence and will.

The modes in which we attempt to control these morbid states, and re-establish natural actions, would seem, then, very obviously to be such as tend to equalize the vascular and nervous actions, simply or conjointly, and in every degree of their functional combination; in other words, to excite or depress, to stimulate or to allay, in every case, as each case may require. In the

* Ipse quoque compluries observavi, motus convulsivos ex vermibus, accedente febre vermibusque per æstum vel bilem acrem enectis, sponte cessasse. Opera omnia, vol. iii. sect. 2, cap. 1. *De optima naturæ morbis medendi methodo*, sect. xxv.

† Dr. Forbes has communicated to us a striking fact of this kind.

practice of surgery, or rather in the medicinal means employed in external affections, we can generally recognise these simple principles; and when to stimulate and when to lower is acknowledged to be so compendious a surgical principle as nearly to include every other. In the treatment of such cases as fall under the physician's care, the principles are, we apprehend, equally applicable, although their simplicity is in some degree hidden by the variety of the phenomena, the frequent obscurity of their origin, and the number of the constitutional and local means employed. If this be so, the Brunonian doctrine erred less in its principle of dividing diseases into two great classes, than in the application of the principle to the actual arrangement of diseases, and in not admitting the simultaneous existence of states compounded of and exemplifying both the divisions.

Admitting the great difficulty of determining in what precise manner medicines produce their least doubtful effects, we plainly observe how both vascular and nervous excitements are sometimes lessened by *evacuants*, general or partial; by general or local bleeding, by purgatives, diuretics, and diaphoretics; and how the evacuant plan is supported by the auxiliary one of diminishing the supplies introduced into the system. It is equally clear that we try to rouse both the vascular and nervous systems by *stimulants*, including various agents exerting a more or less durable tonic power on the contractile forces, or on the digestive function, or directly on the nervous system, or on the vascular extremities on the internal or external surfaces. Several of the agents employed in certain circumstances as general evacuants are local stimulants, which in other circumstances are used simply as such; those, for instance, which excite the bowels, the kidneys, the uterus, or the skin. In some instances even venesection, the most direct evacuant, has the effect of a stimulus, by removing some oppression, as in apoplexy; in other cases, as of nervous excitement connected with vascular disturbance, it is a direct sedative; and in certain states of fever a brisk purgative, by its effects on the intestinal surfaces, acts as a stimulant to the whole system. We are also possessed of means of allaying inordinate actions by medicines which do not act as evacuants, by *sedative* applications. Opium and other medicines of this class are daily employed as auxiliaries to bleeding, and as means of restraining violent muscular actions, or irregular and profuse secretions, or sensations too acute, or mental excitement so great as to be incompatible with repose or with reasonable mental acts. The same substances, in smaller doses, are sometimes used as stimulants; and as irritation is often connected with debility, all stimulants may sometimes be said to act as sedatives. All that belongs to a knowledge of the ordinary properties of medicines of different kinds or in different doses may soon be known; but the great art of medicine (expressed in a well-known and often-quoted saying of Boerhaave,) is the application of the proper medicine in the proper dose at the proper time.

Both in cases requiring evacuants or stimulants, and also in cases of long-continued disorder of any function or organ, leading to structural changes and new formations, the employment of evacuants, of stimulants, or of sedatives, may be so regulated as to produce gradual alterations of action, to suspend actions which are morbid, or to restore, or excite, or regulate actions which are only disturbed. When thus employed, the medicinal means are called alterative, and they have already been spoken of under the head of ALTERATIVES.

There can be no doubt that the operation of medicines prescribed with these intentions is contemporaneously exerted both on the nervous and the vascular system, and generally by a primary influence on the functions of digestion and assimilation.

Besides the general effect of medicines as stimulants, evacuants, or sedatives, they commonly possess, as we have seen, a power of acting locally, from which, in many instances, even their general operation is obtained: the various purgatives act with greater or less energy on particular portions of the intestinal canal, some on the duodenum, some on the colon and rectum, and yet all may be employed as evacuants. But there are a few medicinal substances which seem to exert a still more especial influence on particular parts of the body: it may, perhaps, be said that iodine especially stimulates the absorbent and glandular system; there can be no doubt that the secale cornutum singularly stimulates the muscles of the uterus, and that the strychnine exerts the same power over the whole system of voluntary muscles. We are content therefore to employ these agents empirically.

In a great variety of cases, and for a great variety of purposes, external irritants are employed; to aid in checking acute diseases, and to suspend those which are chronic; to relieve local internal plethora; to free internal parts from painful disorder; to disembarrass, as it were, in some cases, the constitution from superfluous or morbid humours, and prevent their specific irritations of glandular or other tissues. In the familiar instance of cynanche tonsillaris it may often be noted how the scarlet colour of the fauces, with the swelling and other appearances of inflammation, disappear as soon as a blister has been applied with effect to the throat; the relief being plainly attributable here to a simple transference of action. The cough and some of the other symptoms of phthisis are generally, although but temporarily, relieved whenever a pustular eruption is produced on the chest by the antimonium tartarizatum applied in the form of ointment; and this suspension of symptoms is the result, perhaps, of a transference of irritation from the bronchial mucous surface to the skin, rather than of any suspension of the disease itself; although it is often sought to suspend the actions of diseases themselves by similar means, or by setons and issues. When the new actions induced by counter-irritation produce relief from pain, the effect may either be ascribed to a transference of irritation, inducing an altered condition of the nerves, or to the discharge of humours from the circulation, which in such cases were productive of nervous irritation, as in others they seem to be of all the disordered actions of the scrofulous constitution.

As the advantage obtained from alterative medicines appears to be derived through their influence on the functions of digestion and assimilation, and by their general operation on the nervous and vascular system; so, on the other hand, it may sometimes be observed that medicines of great power are singularly modified in their effects by the state of the body at the period of their administration. In the latter case, all the operation of the medicines seems happily directed to a specific movement or alteration in the part of the system particularly affected, and their usual effects on the system at large are placed in a state of abeyance. Calomel, and opium, and wine, have been given to an enormous extent in tetanus, and sometimes in other affections, without salivation, or mental elevation, or oppression. In certain states of nervous irritation, very young children have taken, with advantage, opiates in doses which would have been destructive to them in a state of health. The same observation has been made in the case of adults affected with calculus; the quantity of opium given in such cases having sometimes been governed solely by the relief afforded, and yet producing no effect on the system in general. (Parr's London Medical Dictionary, article *Calculus*.) In hydrocephalus, the power of sustaining immense quantities of calomel has been ascribed to the peculiarly insensible state of the nervous system; but the same power is occasionally seen in cases of croup, although certainly in the latter affection the debility produced by large quantities of mercury sometimes becomes a serious consideration on the decline of the original malady. To these illustrations may be added that afforded by the tolerance of large bleedings, of calomel, and of opium, in inflammatory disorders in general, and of the tartar-emetic in pneumonia especially.

The best approach to the general principles of practical medicine, and the most convincing illustrations of their authenticity, are to be gained by reflecting on the intentions of all the usual parts of practice in the most common examples of disease.

Taking the example of *fever*, the most general morbid affection of the frame, we may perceive that the intentions acted upon are sometimes to check the first depression by direct stimulants and tonics, which is chiefly, if not solely, practicable in fevers of an intermittent type. When excitement supervenes on the first depression, we seek to allay it by evacuants, acting either on the mucous and cutaneous surfaces, in the shape of purgatives and diaphoretics, or on the whole system, by venesection. We lessen the quantity and stimulating quality of the food. When inflammatory actions arise, to these means are added local depletion, or local evacuation, and sometimes sedatives, as the application of cold, or the combination of opium with calomel; and very frequently we resort to some of the forms of counter-irritation: all these means being varied according to the seat of the inflammation. After a certain period the febrile actions decline, the different organs are left in a state of weakness; even the inflammatory affections which still linger behind seem connected with debility: and now we resort more freely to tonics and stimulants, medicinal and regimenal. Throughout the whole course of a disease, various in its forms, in its symptoms, and uncertain in its results, there are certain plain rules for our guidance, few in number, drawn from the existence of certain states of increased, or diminished, or irregular actions at the time. The principles are not obscure, but it is still their wise and timely application which constitutes a good practitioner. In following, for instance, that apparently plain indication of giving tonics or stimulants in the stage of debility consequent on fevers or other maladies, not only is it necessary to commence their administration with exact attention to the proper time for so doing, but delicately to apportion our attempts to the existing strength; according to the ancient and sage maxim, that *debilibus debilia, valentibus valentiora conducunt*, a rule which was supported by John Hunter, when he maintained the principle of not "increasing the action without giving real strength," and that we should always have regard to "the balance which ought to subsist between the power and action of every part." (Treatise on the Blood, &c. Introduction.)

In the course of a fever we find the most remarkable exemplifications of the effect of mental derangement; certain states of the mind seeming to increase or moderate the symptoms of a disease to which they also increase or lessen the predisposition.

There is a very important *sedative* appliance, the effect of which is never so universally observable in fever; although it is not to be overlooked in any affection; namely, *repose* of the affected or disturbed organ. With as much care as the surgeon takes directly to impede the undue use of maimed or diseased extremities or parts of the body, should the physician forbid or obviate the undue exercise of the whole muscular system in a fever; and not only of the muscular system, but of the system of circulation and the nervous system. It is, indeed, in some degree with this view that he inhibits a full or stimulating diet; but he must also prevent, as much as possible, the access of all external circumstances which excite the senses, the mind, the volition, and the locomotive forces. The benefit of this kind of repose in a fever is always in proportion to its extent. In slighter maladies, its use needs no illustration.

In the treatment of *inflammations*, not originating in the state of fever, the same principles are followed; active evacuations during their active stage, combined with various sedative means, sometimes opium, sometimes the tartar-emetic, which, although an evacuant when employed, after the old method, in small doses, is a sedative when given to the extent common in modern practice, and particularly, as has been mentioned, in pneumonia. The chronic forms of inflammation, like those in the latter period of fevers, are sometimes combated by stimulants, external or internal, and these may be simultaneously employed with some local forms of evacuation, and also with sedative agents; the emptying of distended and disordered vessels, the excitement of the vessels themselves, the strengthening of the body, and the expulsion of morbid humours, all requiring to be attended to.

The importance of local applications, both internal and external, is seen to be very great. Even

in acute inflammations they are highly serviceable auxiliaries, and in chronic affections they are often alone equal to effecting a cure. Whilst by general bloodletting and other evacuants we seek to lessen the quantity of circulating fluid, and to lower the energy of the heart, by local means we still endeavour to alter the state of the capillaries; and in cases in which neither general evacuants nor general stimulants are required, local means applied to the internal or external surfaces may perhaps effect all that the case requires. Such is the result of daily experience; and the fact is consistent with the physiological character of the capillaries, the powers of which are to a certain extent independent of the heart; insomuch that they are even exerted for a time after all communication between the capillaries and the heart is cut off. The application of leeches, of blisters, of friction, and of cold and warmth to the body, amply illustrate the action and the utility of local measures in inflammations, in fevers, and in various local affections: and in other cases, diuretics, purgatives, expectorants, emmenagogues, are used with a design of obtaining specific local actions, which are often excited with equal certainty and advantage.

External applications include the various forms of bathing, which may be so ordered as to answer in different cases the purposes of a stimulant, of a sedative, or of transferring vascular and nervous excitement to external from internal parts. (See Bathing.) The use of fomentations is equally applied to all these purposes, to stimulate inactive parts, or to allay pain and inflammation.

When it is the object of our practice to relieve a patient from the inconveniences or threatened dangers of *plethora*, the reduction of the quantity of circulating fluid is in ordinary cases the plain indication or principle which we keep in view; and this we attempt to pursue by direct evacuants, bloodletting, and purgatives which stimulate the capillary extremities in the intestines to the evacuation of fluid; perhaps, also, by diuretics and diaphoretics, which act in a similar manner on the kidneys and skin. These indications may become combined with that of giving tone to the containing vessels; or, more commonly, with that of guarding some particular organ from the effects of determination or congestion; and we fulfil the latter indication by local depletion, by the sedative action of cold, by establishing artificial discharges, and by warning the patient against hurtful exercise or postures. Whilst we try by these means to diminish the quantity of fluid already existing in the body, and to avert its evil consequences, we are careful to cut off the supplies, by a proper regulation of the quantity and of the quality of aliment; and we debar the patient from solid or fluid stimulants which would counteract our evacuating plan. In some cases of congestion, as of the skin, or of the abdominal viscera, the admission of medicinal or dietetical stimulants, and of external stimulating applications, may constitute a part of the indications.

In all the approaches to *anæmia* and to *atrophy*, our principles of proceeding are totally different. To supply proper food, and by cautious attempts to rouse or stimulate the powers on which the digestion and assimilation of that food depend, not only demands every resource of medicine, but the judicious application of the air as a means of renovation, and the careful avoidance of evacuants which would destroy the feeble remains of vitality.

In combating the *profluviæ*, we have to counteract the increased discharge by stimulants which act on the too much relaxed extremities of the capillaries, or we have to lessen the determination to them by new modes of evacuation, or we have to remove their state of congestion by local depletion instead of permitting the evacuating discharge to proceed uncontrolled; and external means are sometimes employed to assist one of these kinds of indication and sometimes another: the direct removal, also, or allaying of the irritation of the capillaries, whether directly or sympathetically excited, is often had recourse to, and by the use of sedatives.

In the case of *suppressed secretions*, whatever may be the cause of the suppression, our means of relieving and removing the disorder are still either vicarious evacuants, or stimulants, or sedatives. Take the periodical uterine discharge as an example. Its suppression is sometimes cured by bloodletting or by leeches; sometimes by purgatives; sometimes by local, sometimes by specific, sometimes by general stimulants, as tonics, exercise, change of air, and diet; and sometimes by sedatives, which remove irritations of the affected organ incompatible with functional regularity.

In violent *nervous disorders*, where at first sight it might appear that our principles of treatment were more numerous, it is found on examination that they are only more complicated than in common cases. In epilepsy, in hysteria, in mental disorders, whether the cause is in the brain itself, or in its blood-vessels, or in some other organ, the means of cure are but the means of evacuation or of stimulation, or of allaying morbid movements, general or local, immediate or remote, occasional or habitual.

In the case of *morbid formations*, and in that of *scrofula*, we attempt to control evident disordered actions in the nerves and blood-vessels, actions not easy to be defined, by diminishing or by increasing the supply of blood or of nervous energy sent to them, by allaying irritations, and by setting up new and controllable actions to oppose and suspend the old.

Hereafter, in these instances of morbid formations, as in those of calculi and of poisoning, very material chemical principles may enlarge our views of practice, and add to our means. These are at present extremely limited, and chemical medicine, of which Paracelsus may be said to have been the founder, is yet in its infancy; indeed it is yet very doubtful if any instances of the successful application of chemistry to medicine can be cited; the chemical medicines, so called, which are employed in cases of calculus, or of simple gastric acidity, not appearing to act as direct chemical agents, but by their influence on the organs of digestion. Yet the detection of some fluid ingesta in the blood, and in the urine, as well as the direct influence of atmospheric air on the blood, are facts sufficient to defend chemical therapeutics from the imputation of extrava-

gance; and we cannot but be of opinion that the improvement of medicine will, during the next century, proceed much in that direction. More accurate investigation of the fluids in a state of health will lead to a fuller acquaintance with the changes effected in them by disease, and it is not forbidden to us to hope that more direct means may eventually be discovered of checking several diseases than we have yet ventured to suppose the existence of. This probability, however, has been recently disputed; the chemists, on the one hand, being accused of expecting too much from their science, and the physiologists, on the other, reproached with a neglect of chemistry. Dr. Thomas Thomson of Glasgow, a chemist of the first reputation, and a man of great knowledge and great wisdom, expressed himself on this subject in the following terms, in a work published a few years ago :—

"I need not observe to those gentlemen who have paid attention to the subject, that by far the most likely means of improving physiology is a cautious application of chemistry to the investigation of the different constituents of the human body. An accurate knowledge of the chemical composition of every organ, and of the alterations produced on that organ by disease, would probably throw new and unexpected light upon the nature and treatment of many diseases. Physiology hitherto has been handled almost exclusively by the anatomists. These gentlemen have acted with a zeal and industry that cannot be too much admired.* * * * * A new and more subtile species of anatomy remains still to be applied. Where the labours of the anatomist terminate, those of the chemist should begin. This chemical investigation of the animal body may be just said to be commencing at present; for it was not till the atomic theory was brought to considerable simplicity and perfection, that such an investigation was possible. It is easy to see that it must contribute prodigiously to the advancement of physiological knowledge."*

More recently, Dr. Prout has expressed himself in terms more sanguine: and to the controversy which ensued between this distinguished pathologist and Dr. Wilson Philip, a physician who stands peculiarly characterized by the philosophical spirit with which he has cultivated physiology, pathology, and the practice of medicine, the reader might with less hesitation be referred, if the discussion had not provoked more discourtesy than should ever be shown by great improvers of science, to whom truth alone should be of any real consequence.† All parties and all authorities will, we believe, at least concede that chemistry may and will prove a valuable auxiliary to physiology and to pathology; and that its subsequent application to the treatment of diseases may not unreasonably be expected. No one will be found, we imagine, to contend that chemistry will ever explain every thing in physiology, or that the practice of medicine will ever rest on chemical principles alone.

[Of late, increased attention has been paid to chemistry, owing to the researches in organic chemistry of Liebig, Boussingault and Dumas, and others; but they do not modify the inferences expressed above.]

There is much reason to believe that the advantage derived from medicines in some states of disease arises from the changes they effect in the intimate elaborations carried on within the blood-vessels, and of which the products are the various healthy and morbid secretions. Such would seem to be particularly the case in the instance of specific inflammations; and the same is very probably true as respects several or all of the morbid formations. The disposition of a scrofulous constitution towards the formation of tubercles is probably connected with as definite a change in the character of the blood as that which more palpably, and by general acknowledgment, exists in chlorosis and in scorbutus, in some fevers, and in the Asiatic cholera. In many of these cases, as well as in colica pictonum, and in the tremours produced by exposure to mercurial fumes, it cannot at present be decided how far the supposed sanguineous detriment exists, or if existing, to what extent it is combined with, or even dependent on, injury of the nervous system.

In several disorders which the pathologist unhesitatingly admits to be nervous in their character—in tic douloureux for example—the cure by specific modes of treatment seems to depend on some change wrought in the condition of the nerves or nervous system itself different from mere sanguineous excitement or congestion, and different from deficient supply of blood. The whole subject of nervous pathology is in great obscurity. It is possible that the minute ramifications of the several nerves may possess various properties as distinct from and to as great a degree independent of those of the larger nervous masses as are some of the functions of the capillaries from those of the heart; and a knowledge of such properties, if existent, must be preliminary to any near approach to correct principles of treatment in nervous disorders.

A few medical applications require to be separately alluded to, as being employed on mere mechanical principles;—demulcents in irritations of mucous passages; some of the anthelmintics, as the filings of tin; and various emplastra, when the intention is to give support to subjacent or neighbouring parts. None of these require further observation.

The principle of treatment sometimes recommended in chronic and obstinate diseases, and spoken of in the article disease, that, namely, of producing some strong impression or commotion of the system, in the hope that the system may, in such an artificial and general disturbance, rectify or *right* itself, might, in different cases, produce its advantages by acting on the nervous or on the vascular system, or on both. As views of treatment become more and more understood, such treatment, however, will be less and less resorted to; and if sudden and violent measures should be thought desirable in lingering states of disorder, the principles of their application and use will be better comprehended. It may be observed

* An Attempt to establish the First Principles of Chemistry by Experiment. By Thomas Thomson, M. D. Regius Professor of Chemistry in the University of Glasgow, &c. &c. Lond. 1825. Introduction.

† See the Report of Dr. Prout's Gulstonian lectures, and the whole controversy, in the Medical Gazette for 1831; also a paper in the same volume by Dr. Stevens, on the Treatment of Malignant Diseases.

that much of the success of irregular practitioners seems no less to depend upon this principle than that part of the benefit often ascribed to the use of various mineral waters arises from the general change of diet, regimen, and habits of life, with which a temporary residence at watering places is almost in all cases accompanied. The principle by which these circumstances effect favourable changes in the health seems especially deserving of consideration, both in such cases of chronic disorder as are connected with morbid conditions of the nervous system, including those which especially and in various degrees affect the mind; and in all diseases which depend upon, or which have induced, an altered condition of the blood.

Careful consideration will generally show, even in chronic, and obstinate, and anomalous maladies, some clear indications to be followed for the relief of the patient; and in the cases in which any expectation of a perfect cure is to be indulged, the means of effecting it can hardly ever be wanting to those who can reasonably entertain the expectation. The very principle on which relief seems sometimes to be obtained by changing the habits of the patient in many particulars, may perhaps be found, if inquired into, to be resolvable into that of removing some unexpected cause of irritation, which removed, digestion and assimilation, and the proper distribution of venous and sanguineous energy are restored, and the balance of health is regained. The *means* of relief will still be found to have been something which has imparted power or stimulus to overcome the morbid obstacle, or something which has directly allayed some morbid irritation; or, lastly, something which has produced a delayed or much required evacuation of some morbid material, or something which has improved the state of the blood. The principle of relieving long-continued ailments by attention to the digestive organs is spoken of by Dr. Heberden in his Commentaries.* It has of late years gained much attention in this country, and still more on the continent, insomuch that practitioners have not been wanting who have ascribed every possible disorder to primary digestive derangement. A direct improvement of the blood is a very probable consequence of such a plan, and various ameliorations of nervous and vascular actions may follow, or may only accompany this change.

The first *principles* of practical medicine, then, are few and simple. In a work every article of which is an illustration of those principles, we need not dwell longer on the principles themselves. It may almost be said, employing the words of Hoffmann, that there is no other method of cure, and that there should be no other intention in the physician, than to reduce to order the actions and excretions when not in a natural state; and that all kinds of medicines do but this, to allay actions which are excessive, and excite or promote and equalize those which are depressed and obstructed.† But the *means* of fulfilling these indications are very various; and if the judgment of the practitioner is exercised in their application, so their increase and diversified combination afford equal scope for his ingenuity and invention. Departing from all rational principles, physiological or pathological, the physicians of the middle ages vainly sought some universal medicine which should accomplish every varied indication at once. Such dreams have long ceased to be indulged in, although some base pretenders yet insult the public sense by professing them; and the only hope of attaining to principles of universal application depends on the gradual improvement of our knowledge of all the actions of the body in health and disease. The principles of medicine, not dependent solely on a doctrine of solidism or of the humours, lead, therefore, to no extreme and exclusive practice; and the influence of the moving powers is admitted without excluding just views of their solid and fluid results. The mutual dependences of the nervous and vascular energies, and the properties of and changes effected in the blood, being all taken into consideration, we admit nothing but what is known, and wait for further explanations from the constant progress of all the sciences connected with medicine.

From early infancy even to extreme old age, the few principles now enumerated seem at present to be the constant guide of our art in its attempts to rouse, to regulate, or to appease, actions insufficient, or too disorderly, or too energetic, to be consistent with comfort, with freedom from uneasiness and pain, or with the maintenance of health and strength of body or of mind. In all the varieties of their application, the object is to restore healthy actions as soon, and with as little waste of strength, and with as little suffering as possible: or, as a fashionable physician of ancient Rome was in the habit of professing to do, *cito, tuto, et jucunde:* and where a cure is out of the power of our art, the same principles lead to means of relief by which life is made comfortable for a long period, during which the patient if left to nature would be consigned to misery. The time *may* come, when, guided by yet undiscovered knowledge, and new and more direct principles, the tendency to tubercular and other morbid formations may be surely checked; chronic inflammations readily cured; and fever suspended in its first movements. But the day of these triumphs is yet distant.

Hoffmann mentions it as the first criterion of a man skilled in the medical art, to know "*cur et quare* hoc vel illiud alimentum ad valetudinem conservandam morbosque sanandos salutare vel minus tale sit dicendum;" and he quotes with deserved praise the eulogium of Thuanus on Hollerius, a famous physician of Paris, who by constant meditation had so improved his judgment, that he often cured those ill of such deplorable maladies as the other physicians of the time, "riding rapidly through the streets," (per vicos vaga cursitatione mulos fatigantibus,) knew little or nothing about. We may confidently recommend to the student the diligent perusal of the works of the admirable

* De Ratione Medendi. See also *Baglivi*. In chronicis pauca remedia requiruntur ——— semper tamen in morborum diuturnitate consulendum est digestionibus. Animadv. Pract. Nov.

† Neque aliam dari medendi viam, vel etiam medentum debere esse intentionem, arbitramur, quam ut motus et excretiones, a naturali statu desciscentes, in ordinem reducant. Omnia enim remediorum genera id tantum præstant, ut vel nimis auctos motus sedent ac moderentur, vel depressos et impeditos excitent, promoveant et rursus æquales reddant. *Opera omnia*, Præfat.

physician whom we have here and already more than once quoted in this article. His learning and admirable good sense, the liberal spirit in which he viewed all parts of medicine, his discrimination as regards the innumerable controversies existing in his time, his wise direction of the medical practitioner's mind to things concerning which the senses could give information, things useful and about which men could speak reasonably,—"quæ in sensus incurrunt, quæ usum habent, et de quibus evidens ratio constat et dare potest,"—rather than to subtile disquisitions relating to things more obscure;—these and many other merits have not only endeared his name to learned physicians, but to liberal scholars, from the time when his writings appeared to the present day. Notwithstanding the subsequent undoubted advancement of medicine, there are few pages of his voluminous works to which the practical physician may not yet refer with advantage.

The number of writers in whose publications any specific notice of the abstract principles of medicine is to be found, is not very great. We do not mention writers professedly on the practice of medicine, whose works are like the separate articles of this work, *illustrations* of principles. Many valuable observations occur in Baglivi, (Opera Omnia, Lugd. 1733), and many ingenious ones in Cabanis, (Du Degré de Certitude de la Médicine); the works of M. Broussais, amidst much false and much doubtful theory, contain views and principles both original and important. In Dr. Heberden's Commentaries will be found a sensible chapter, De Ratione Medendi, and another in Dr. Gregory's Conspectus Medicinæ Theoreticæ, with the same title. Dr. Burne made it the subject of an excellent oration delivered to the Medical Society of London a few years ago, and since published. And we may mention, that in the Outlines of Pathology, just published by Dr. Alison, the English reader is for the first time presented with so clear, condensed, and comprehensive a view of the whole subject of *disease*, as can hardly fail to lead those who read it with care and reflection to a knowledge of the principles by which their practice should be regulated in all diseases.

At the same time, no reading nor reflection can make a good practitioner. Like an able orator, he must add to all the rules of his art daily habit and practice. His mind must be continually presented even with *numerous* examples and illustrations to guide and assist his judgment, and to correct the errors of reasoning on a practical subject. The symptoms of disease may be well understood and remembered, and the general principles of practice; but the treatment of diseases comprehends a multiplicity of details, essential or indispensable to the cure, and yet which easily, or almost inevitably, escape the memory of him who, although thoroughly grounded in the principles of medicine, is not continually exercised in prescribing for the sick.

The great utility of teaching by examples, selected at the bed-side, or by what is called clinical teaching, so long neglected in this country, and for the introduction of which we owe so large a debt of gratitude to Rutherford and Cullen, begins to be universally acknowledged. The full benefit of this admirable method will be the inheritance of another generation. A long existing defect in this respect has doubtless obscured the principles of practice, and in many instances quite shut them out of the practitioner's view during his whole life.*

But, if so engaged and so prepared,—by the principles already mentioned, and by others hereafter to be discovered, or by additional means of fulfilling the indications of medicine, the practitioner of the medical art has the privilege of feeling assured that he is useful; and the art itself, thus guided, and in every stage of its imperfection even to its final advancement, will continue to be of most singular service to mankind; relieving the sick, to use the expressions of Hippocrates, from the greatest of evils, from diseases, from pains, from sadness of mind, and from death.

By no one circumstance, we would add, will the practitioner find himself more assisted in his practical efforts, more enriched in practical resources, and better able to command them in all emergencies, than by the cultivation of a sincere and anxious desire to relieve his patients from whatever physical evils oppress them:—in all the varieties of his practice, no other feeling will so surely and so happily stimulate his mind.

J. Conolly.

MELÆNA.—This name (*μέλαινα νοῦσος*, the *black disease*,) was adopted by Sauvages from the writings ascribed to Hippocrates, to designate a genus of disease which he defines, "Alvifluxus materiæ nigricantis, atro-rubræ, dejectione aut vomitione frequenti notatus;" and this is the sense in which it is generally employed by modern nosologists and practical writers. We mean, therefore, by melæna, the occurrence, *as a symptom* in any disease, of very dark-coloured, grumous, pitchy, often highly-fetid evacuations by stool, commonly joined with sanguineous vomiting; or we use the word *as the name of a disease* in which such evacuations, with or without vomiting of blood, constitute the characteristic symptom. In these two senses authors speak of *symptomatic* and *idiopathic* melæna; but even where the latter phrase is with most propriety employed, the hemorrhage may generally be traced to some constitutional disorder or local organic disease as its primary cause. It has been mentioned in the article Hæmatemesis, that there is so close an affinity between that disease and melæna, that often they are not easily to be discriminated. Hæmatemesis is properly an hemorrhage from the mucous membrane of the stomach, and is *chiefly* characterized by vomiting of blood: melæna properly consists in hemorrhage from the mucous membrane of the small membrane, and is *chiefly* characterized by the dark evacuations by stool which have just been described. But as

*For an account of Dr. Cullen's clinical teaching in Edinburgh, the reader is referred to Dr. John Thomson's recently published life of Cullen. Every pupil of the great school of Edinburgh must rejoice to see the reputation of one of its greatest founders, and one to whom practical medicine is so immensely indebted, placed in its true light by a man of learning and science, and rescued from the superficial criticism in which it has of late years been too much the habit of a certain class of writers and lecturers to indulge when mentioning Dr. Cullen's practical works.

these two symptoms very frequently concur in the same case,—as blood poured out by the stomach is often carried downward into the intestines, and blood effused in the duodenum may pass upwards through the pylorus into the stomach; and as, moreover, these two hemorrhages are so much akin to each other in their seats, their causes, pathology, and treatment, a distinction between them is not always easy, and is seldom practically important. There exists, however, sufficient distinctions between them in all these respects to make it proper to treat of them separately in a system or a dictionary of medicine.

Synonymes. Μέλαινα νοῦσος? (*Hippoc. de Morbis*, lib. ii.) Morbus niger; Fluxus spleneticus; Melæna splenctica (*Sauvages*); Secessus niger (*Hoffmann*).

The description of the μέλαινα νοῦσος by the author of the treatise "On Diseases" ascribed to Hippocrates, is rather a matter of literary curiosity than of any practical importance. It is in the following words, translated as literally as the English idiom will permit:—

"The patient vomits black bile (μέλαιναν), resembling lees of wine; at other times a matter resembling blood. Sometimes the matter vomited resembles the *second* wine, (οἶνον τὸν δεύτερον, that obtained by putting the grapes into the wine-press:) sometimes it is like the ink of the cuttle-fish; sometimes it is acid, like vinegar; sometimes it consists of saliva and thin phlegm; sometimes of greenish bile. When the black blood-like matter is vomited, it smells like putrid or sanious blood (δοκεῖ οἷον φόνου ὄζειν). The fauces and mouth are scalded by the acrimony of the vomit; it sets the teeth on edge, and effervesces with the earth on which it falls; (this is probably the meaning of τὴν γῆν αἴρει.) When the vomiting is over, temporary relief ensues; but the patient cannot bear either emptiness or fulness of the stomach, the first causing flatulence and acid eructations, the latter a sense of weight at the præcordia, and a feeling as if the breast and back were pricked with sharp instruments. There are aching pains of the sides; a slight fever; the sight grows dim; and the patient is unable to stand. His complexion turns dark-coloured, and he becomes emaciated." Such is the description of the disease: the treatment it is unnecessary to give at length, even were it possible to render it faithfully. As far as we can understand it, it consisted in purgatives given frequently, (φάρμακον πιπίσκειν θαμὰ,) emetics, (φαρμακοποσίας τὰς ἄνω,) and afterwards venesection, if not forbidden by debility; a diet of whey, milk in the proper season, and whatever is cooling and laxative, excluding sweet, oily, and rancid articles; emollient clysters, if required on account of costiveness; a great quietude, and regularity of regimen. "If these things be done," adds our author, "the disease, as age advances, is removed, even if it remains in the habit till old age. But if the skin assumes a dark hue, it (quere, the colour or the disease?) will continue till death."*

* *Hippocrat. περὶ νούσων*, lib. ii. ad finem. Opera, p. 486, edit. Foësii, Genevæ, fol. 1567. The writer of this article has had the kind assistance of a friend distinguished by his philological attainments in revising the above translation. The last passage is scarcely intelligible, but seems to indicate that the disease in question is one of a very chronic nature and slow of removal; ταῦτα ποιεῖν· καὶ ἅμα τῇ ἡλικίῃ ἀποφεύγεται καὶ ἡ νοῦσος, εἰ καὶ καταγήρασκει σὺν τῷ σώματι· ἢν δὲ μελανθῇ, συναποθνήσκει. The two other diseases, called ἄλλη μέλαινα νοῦσος, and σφακελώδης (νοῦσος) have nothing to do with our present subject.

It is remarkable that the above description contains not a word respecting the black discharges by stool, which, with Sauvages and the moderns, characterize melæna, though this sympton (ὑποχωρήματα μέλανα, δκοῖον αἷμα) is often mentioned in other parts of the Hippocratic writings.

Hoffmann treats at considerable length of hæmatemesis and melæna, the latter of which (vomitus cruentus *cum secessu nigro*) he considers by far the more dangerous form of the disease, and identical with the morbus niger of Hippocrates. (Opera Omnia, tom. ii. p. 214.)

Sauvages introduced the name of melæna to denote this particular disease. He makes it a distinct genus, and assigns to it several species, some of which appear to be founded on observation, if not on correct pathology; others are hypothetical and fanciful.

Although Cullen has omitted melæna in his catalogue of diseases, he gives some account of it in his "First Lines," principally with reference to its pathology.

Morgagni, Haller, Lieutaud, Tissot, (Epist. ad Zimmermann. Epistolæ Medico-Practicæ, 12mo. Lausannæ, 1782,) but especially Portal, (Mémoires sur plusieurs Maladies, tom. ii. pp. 129, seq.) have, among continental writers, mainly contributed to advance our knowledge of the history, pathology, and treatment of this disease. The series of cases and dissections recorded by Portal are particularly worthy of diligent perusal.

In the publications of our own country, Dr. Francis Home, (Clinical Exper. and Hist. p. 127,) Dr. Marcard, (Edin. Med. Commentaries, vol. iv. p. 203,) and more recently Dr. Brooke (Irish College Transactions, vol. i. p. 124,) and Dr. Cheyne (Dublin Hosp. Reports, vol. i. p. 259,) of Dublin, Dr. Ayre, (On Marasmus, pp. 113, 117, first edit. 1818,) and Dr. Belcombe, (Med. Gazette, vol. iv. p. 109,) have recorded instructive cases and dissections of this disease. But there are few subjects in pathology which stand more in need of fuller and more careful investigation.

General history and symptoms.—Melæna, as well as hematemesis, so generally occurs as a symptomatic affection, that a description can hardly be framed which shall embrace all the various symptoms by which it is accompanied, according to the various causes which produce it. A much better notion of these will be gathered from a perusal of the cases above referred to, especially those so admirably detailed by Portal, than from any general description. The following may, however, be taken as a comprehensive view of the usual course of what has been termed idiopathic melæna.

The patient has for a considerable time shown symptoms of progressive constitutional disorder; the functions of the stomach have become debilitated; those of the liver and the bowels are imperfectly and sluggishly performed. The countenance has assumed a sallow, dusky, or "leaden" hue; the adnatæ of the eyes have become dull or

greenish; the tongue is furred and clammy, or more or less dry; the breath often tainted. The pulse is habitually frequent, or is periodically accelerated towards evening; in other cases it is intermitting and irregular; and there are palpitations of the heart, or a pulsation at the epigastrium. The symptoms altogether are those of aggravated dyspepsia, to which are often superadded those of visceral congestion. On examination of the abdomen there is to be felt a circumscribed enlargement of general tension and fulness in one or more of the abdominal regions; sometimes also tenderness to the touch. Upon the occurrence of any exciting cause of hemorrhage, an attack of melæna is induced, which is most commonly, but not always, accompanied by hematemesis, and at any rate with the same or very analogous symptoms. After complaining of much præcordial oppression and anxiety, tensive pain of the hypochondria, or dull pain at the scrobiculus cordis, with nausea, general uneasiness of the abdomen, and more or less tormina,—together with the common hemorrhagic symptoms of giddiness, coldness of the extremities, a tendency to faint, &c.—the patient is suddenly seized with vomiting of dark-coloured blood, together with a discharge, by stool, of blood of the same appearance, or more frequently of a very dark and often extremely fetid semi-fluid mass, of the consistence and colour of tar. Sometimes this discharge by stool occurs without any vomiting: it is invariably accompanied by great faintness and exhaustion. Occasionally the black matter discharged by stool is mixed with blood of more unequivocal appearance, or with dark-coloured bile, which may be distinguished from the former by dilution with water; which brings out a yellowish or greenish tinge. In some comparatively rare cases, the matter discharged by stool and vomiting is of a sooty blackness, (οἷον πόλυπον θολὸν, Hippoc.) has no smell, and assumes neither a bilious nor sanguineous tinge on dilution with water: this appears to be the true *melanosis* of the ancients. For some time after the cessation of the hemorrhage the patient remains in a very weak and precarious state, extremely liable to its recurrence, and requires to be carefully watched. Even after the attack appears to be entirely over, a predisposition to its return remains, and unless this be overcome by medical treatment, or by the resources of the constitution, it will in most cases ultimately prove fatal.

Appearances on Dissection. — Although a considerable number of dissections of patients who have died of this disease have been recorded, the subject is one which stands in need of much further investigation with a view to a satisfactory pathology of the several varieties of melæna and hematemesis. It is sufficiently established, by the researches of Portal, Andral, and other morbid anatomists, that no lesion of the mucous membrane of the stomach and intestines, except in some very rare cases, is to be met with in cases of gastric and intestinal hemorrhage. (See HEMATEMESIS.)

In a few cases partial reddening, softening, and oozing of dark-coloured fluid (similar to that discharged during the disease) is stated by Portal to have been observed in the villous membrane of the bowels. Morgagni records a case where the whole tract of the intestines was found "horribly inflamed." But much more frequently no trace of disease is discovered in the stomach and intestines; these organs have on the contrary been found remarkably pale and exanguious, (*Morgagni*) while marks of congestion appeared in the turgescence of the mesenteric and gastric veins, loaded with dark-coloured blood. (*Portal.*) Chronic enlargement or structural disease of the liver and spleen has been found in cases where the symptoms had led to suspect them to exist during life. It is highly desirable that in future investigations not only the state of these viscera be most carefully examined, but also the condition of the circulating system, and especially of the heart and great vessels, morbid alterations in which have only of late begun to attract a proper degree of attention, as causes of venous congestion and of *passive* hemorrhage.

Causes.—The predisposing and exciting causes of gastro-intestinal hemorrhage have been pretty fully considered in the article HEMATEMESIS, and therefore it is not necessary to prolong the present article, by recurring at any length to this part of the subject. Organic disease, a cachectic or greatly debilitated state of the constitution, sedentary employment, intense anxiety and close application to business, and a full and stimulating diet, with neglect of air and exercise, are the most usual predisposing causes, to which must be added fretfulness and irascibility of temper. These causes are most apt to induce a predisposition to melæna in males about the age of forty-five or fifty, in females about the time of the cessation of the menstrual periods. The exciting causes are those which occasion hemorrhage in general, as intemperance or any kind of excess, but especially any violent mental emotion or struggle, and none so frequently as a burst of passion. This has often induced not only a first attack of melæna or hematemesis, but the same cause has given rise to its recurrence at several times, when the patient seemed to be going on favourably, and to the final catastrophe, by bringing on a last and fatal attack. This is well illustrated in Portal's first case, (that of the botanist Aublet,) and furnishes a most important caution as to the *moral* management of patients who are predisposed to, and especially who have already suffered from this disease. Irritating and drastic purgatives are well known to occasion bloody stools, when injudiciously employed, and sometimes when given with every proper precaution: but they can hardly be supposed to induce a true attack of melæna, unless where a great predisposition exists.

Varieties of Melæna. — It is important in melæna, as in hematemesis, to distinguish with as much accuracy as possible the varieties which exist in the disease, or the *species* into which it may be distinguished, according to the nature of its causes, the kind of constitution in which it occurs, and the series of symptoms which precede or accompany it. It is evident that on such discrimination alone, a rational pathology or judicious therapeutical system can be founded. The fullest and most accurate enumeration of these varieties which has yet been made, is that of Portal. (Op citat. p. 211.) His species are the following:-

1. melæna supervening in *acute* (continued) fevers; 2. preceding, accompanying, or following intermittent fevers; 3. supervening on strong mental emotion, cases of which are so common; 4. following suppression of hemorrhoids or other habitual evacuations, and especially supervening on the cessation of the menses; 5. depending on the effect of gout upon those organs in whose substance the vena portæ is ramified; 6. that arising from scurvy, whether from this disease occasioning, as it often does, congestion of the spleen and liver, or from an alteration in the quality of the blood; 7. occurring in dropsy, either from the compression produced by the fluid effused in the abdomen, or from the accompanying organic disease of the liver, spleen, and other viscera. This division is evidently not strictly pathological, but it is much preferable to that of Sauvages, and may be useful to those who have leisure and opportunity for a further investigation of this very important subject. Portal illustrates each of his proposed species by reference to his own cases, and to some instances furnished by other authors. Pinel's division into species, of hematemesis, (Dict. des Sciences Médicales, art. Hématemèse, tom. xx.) (under which he comprehends melæna,) may also be consulted with advantage, but not implicitly adopted. Dr. Mason Good's division of melæna into two species, (melæna *cholæa* and melæna *cruenta*,) appears captivating by its simplicity; but he is evidently mistaken when he professes to derive it from Hippocrates; and moreover he starts with a generic definition totally at variance with the usual acceptation of the term melæna, and which seems to rest wholly on the dark hue of the skin, the only circumstance common to melæna, (the melæna *cruenta* of Good,) and the green jaundice described by Dr. Baillie, (his melæna *cholæa*.)

Pathology.—This branch of the subject has been in a great measure anticipated in the article Hematemesis. It may, however, be useful to take a brief review of the opinions which have been adopted respecting the nature of melæna by pathologists. The notion universally entertained before the time of Hoffmann and Morgagni, was that melæna depended on a flow of *black bile*, or of dark venous blood (for these terms seem to have been almost convertible, *bilis atra*, *melancholicus humor*, *fæx sanguinis*, &c.) from the spleen, which was supposed to be its great reservoir, into the stomach and intestines, through the veins called vasa brevia. The latest supporter of this opinion was Van Swieten; but it is not very easy to understand what he means by *atrabilis*.

According to Hoffmann, melæna consists of a true hemorrhage from some of the viscera of the abdomen, most commonly from the small intestines; but in conformity to the notions of his time, he conceived that this could only take place by the *rupture* of a vessel. He therefore supposes that the branches of the meseraic veins ramified on the inner surface of the ilcum are ruptured in consequence of impediments to the return of the blood through these veins, in hypochondriacal and hemorrhoidal subjects, in whom this disease, he says, chiefly occurs; from which impediments follow "distensions, spasms, and congestion in those vessels, and finally effusion." (*Hoffman*, op. citat. p. 214.) Cullen adopts Hoffmann's view of this disease: he considers it to be a *venous* hemorrhage, from obstructed circulation in the vena portæ and its branches; he thinks that its causes are of the same nature with those which give rise to the hemorrhoidal flux; but does not deny that in some cases there may be a true *atrabilis*, producing the symptoms of melæna. (First Lines.) Portal chiefly differs from Hoffmann and Cullen, in referring hematemesis and melæna to *arterial* hemorrhage from the stomach and intestines, occasioned by the afflux of blood by the arterial branches being greater than the corresponding veins can take up; maintaining that this is mostly owing to the compression of the trunk or branches of the vena portæ, occasioned by obstructions not merely of the spleen, as was formerly thought, but also of the liver, pancreas, mesentery, and other viscera of the abdomen. The opinions of Portal, modified by the doctrines of Bichat and his school, respecting arterial exhalation from mucous membranes, constitute the now generally adopted pathology of melæna and hematemesis. (See Hematemesis.) The dark colour of the blood, as has been observed by Portal, (and the observation is as old as Aretæus,) does not prove that the blood is derived from the veins, for the fluid and gaseous contents of the alimentary canal will act upon it after it is poured out, and deprive it of its bright colour. Perhaps this explanation of the intense blackness and pitchy appearance of the stools in melæna, is not quite satisfactory. Dr. Ayre has ingeniously contended, that as no trace of lesion is generally found in the mucous membrane on dissection, the hemorrhage which constitutes melæna and hematemesis does not take place from the capillary exhalants of the mucous membrane, but from the extreme minute ramifications of the vena portæ in the glandular texture of the liver. He argues that a certain degree of congestion of that important viscus will occasion an excessive and vitiated secretion of bile, constituting the common autumnal cholera, and the various modifications of bilious disorder; but that when this congestion occurs in a still greater degree, the extreme branches of the vena portæ are so distended that they cease to secrete bile, and pour out the dark and highly carbonized blood which oppresses them, unchanged; that this is taken up by the biliary pores and conveyed by the gall-ducts to the duodenum, whence it either regurgitates into the stomach, or is carried down the course of the intestines. Dr. Ayre conceives, therefore, that melæna and hematemesis scarcely differ, but in degree, as to the pathological condition which occasions their symptoms, from cholera and other bilious disorders; and he accordingly proposes the same treatment for both. (Ayre on Marasmus, 1st Edit. 1818.) These views are certainly ingenious, and, if established, would be highly important. But the arguments adduced by Dr. Ayre in his work are not conclusive; and his theory must still be considered as an hypothesis which may not impossibly afford the true explanation of *some* cases of hematemesis and melæna, where there is evidence of hepatic congestion existing in a great degree.

The pathology of melæna is still an obscure and very interesting object of inquiry. It is highly probable that in certain cases it depends not so much on mechanical obstruction and congestion

of the blood in the veins of the abdominal organs, as on a change in the physical and perhaps vital qualities of the blood itself, (*Andral*, Pathol. Anat.) which gives it a tendency to escape every where from its vessels. Such a state seems manifestly to exist in certain cases of purpura and of scurvy, in fevers of the typhoid type, and in some malignant varieties of small-pox, in all of which melæna, as an occasional symptom, occurs. Fully to develop this as yet mysterious condition of the blood, its dependence on the state of the nervous system, its connection with the nature of fevers and other diseases, is a problem of the greatest importance and difficulty in pathological science.

Though we have considered melæna as altogether a hemorrhagic disease, yet it may be proper to notice two cases in which the symptoms may closely resemble those of hemorrhage, yet not be truly such. The first is a discharge from the intestines of very dark and putrescent bile secreted in abundance from some irritation or congestion of the liver; the second, a truly *melanotic* discharge, proceeding (as supposed by Dr. Marcard in the case related by him,) from the breaking down of what he calls an atheromatous encysted tumour, in fact a mass of melanosis, either connected with the liver or alimentary canal, or else perhaps from a secretion of matter of the same kind from the mucous membrane of the stomach and intestines. The production of melanosis is not well understood. Does it consist of blood very little altered? Is the black matter vomited in cases of scirrhus pylorus for a considerable time before death, of the nature of melanosis?

Melanotic matter is distinguished from the sanguineous dejections of melæna by the absence of smell, and by the effect of dilution with water. The latter circumstance distinguishes it also from bile.

[A variety of melæna would seem to be produced by morbid secretion from the mucous follicles, (Copland, *Dict. of Pract. Med.*, art. Melæna;) and of this nature are, doubtless, the black discharges, which the writer has repeatedly seen, where the lining membrane of the intestines has been long irritated under the use of mercurial and other cathartics.]

Diagnosis.—Except the two cases just mentioned, and that of hematemesis, the discrimination of which from melæna (as they may jointly occur, and at any rate require similar treatment), is not practically important, melæna cannot require to be distinguished from any other affections, except hemorrhage arising from ulcerations, wounds, and injuries of the intestines, (which are not properly to be referred to melæna,) and the hemorrhoidal discharge. From the latter, where any necessity arises for discrimination, a better diagnosis cannot be laid down than that of Hoffmann, who says that melæna is to be distinguished by the tormina and spasmodic pain by which it is accompanied, and the imminent danger of death in which it places the patient, whereas the hemorrhoidal discharge is free from spasmodic pain of the bowels, and brings relief to any uneasiness which previously existed. Ulceration of the bowels is known by peculiar symptoms, which will be pointed out in treating of that affection.

Prognosis.—Melæna is almost always a symptom portending considerable danger. The only exceptions to this are where it occurs as a truly *critical* hemorrhage in fevers, or where it is attendant on hematemesis in young and plethoric females of unbroken constitution, and with vicarious or suppressed menstruation. The profuse discharge of blood, the debilitated state of the system in which it often occurs, and the organic diseases with which it is apt to be complicated, are the circumstances which constitute the danger by which its degree is to be estimated. The putrescent blood effused into the intestines and stagnating there, acting as a poison upon the nervous system, or re-absorbed into the circulating mass, was thought by Hoffmann to be the chief source of danger in this disease; and hence the great stress which he and others of the continental writers laid on clearing out the bowels by laxative clysters.

Treatment.—In the treatment of melæna, we have to deal with an intractable and too often an incurable disease, and almost always with an enfeebled and exhausted habit. Organic disease is always to be suspected in chronic cases, and where the disease occurs in advanced life, or in persons much exhausted by sedentary labour and anxiety, or weakened by intemperate habits, it is commonly a symptom of what is popularly but expressively termed "a breaking-up of the constitution." There is, therefore, little scope for active, much less for *heroic* remedies. Both during the hemorrhage and in the intervals, or after its cessation, the greatest quiet is to be enjoined; all disturbance of mind or body is to be sedulously avoided. The strength must be supported by the mildest nourishment, in such regulated quantities as not to disturb the stomach. The bowels must be kept open by the gentlest means, as castor-oil and mucilaginous clysters; nervous irritation is to be allayed by camphor and hyoscyamus. Opium and stimulating anti-spasmodics are to be avoided. Refreshing and antiseptic beverages, as lemonade, whey, &c. may be allowed in moderation; wine only where the debility is such as to require it, and where there is no febrile movement in the pulse; regard being also had to the constitution and previous habits of the patient.

Respecting astringents, we may refer to what has been said in the article on Hæmatemesis; observing only that they must in the case of melæna be employed with still greater caution. This applies especially to the more powerful remedies of this class. The mineral acids are useful rather as refrigerants and gentle tonics than as astringents. Where more of a styptic effect is required, the diluted sulphuric acid should be preferred; where a tonic or alterative effect is wished, the nitric. Dr. Mason Good recommends in preference the vegetable acids, and particularly the acetic. The remedy which has acquired the highest reputation as a styptic in melæna is the oil of turpentine. It appears to have been first recommended by Mr. Adair, in the fourth volume of "Medical Facts," &c. Dr. Brooke, of Dublin, and Dr. Cheyne, have since published cases illustrative of its employment, which have been already referred to, and Dr. Elliotson, in his published lectures, has borne testimony to its usefulness. Dr. Brooke gives three cases, in all of which the

hemorrhage was effectually and promptly arrested by the remedy when other treatment had failed. One of his patients died shortly afterwards, but the case was one of long standing, and probably connected with organic disease of the stomach; but this could not be ascertained, as inspection of the body was not allowed. The other two cases were doing well at the date of the paper, but only a short period had elapsed. It is evident that the oleum terebinthinæ, however successful in arresting the hemorrhage, has no influence on the primary cause of the disease, and therefore can be esteemed only a valuable palliative remedy. The formula employed by Dr. Brooke was the following:

℞ Olei terebinthinæ, guttas xxv.
Aquæ cinnamomi, f.℥i.
Syrupi aurantii, f.℥i.
M. fiat haustus ter die sumendus.

In Dr. Cheyne's case the result was less favourable, but the circumstances of it are not the less instructive, especially as it illustrates a caution given by Hoffmann, that astringents given in melæna are, in cachectic habits, likely to produce "a sudden transition to dropsy." A profuse melæna had continued two days. The patient, (a tailor, aged twenty-four, and of cachectic habit,) was growing weaker and weaker, when a "small dose" of ol. terebinth. was ordered to be taken every second hour. Dr. Cheyne does not state how many doses were taken; but it stopped the hemorrhage, but at the same time "seemed to lock up the bowels, so that for nearly three days he was without a stool, his abdomen all the while increasing in bulk. On the 16th, (the ol. terebinth. had been prescribed on the 11th,) there was evident fluctuation, and the stools, when at length obtained, consisted of hardened colourless fæces. First, crystals of tartar, then blue pill with squills, were given, which last affected his mouth in two days, and were discontinued. On the 28th, having taken a purgative, the hematemesis and melæna recurred; it continued two days, and the tension of the abdomen diminishing, he grew very weak and faint, and died on the 30th. The dissection is given at length, but need not be inserted here. Dr. Cheyne candidly owns that the treatment in this case was too energetic; that with more of *expectancy* the patient might have lived longer. This is an instructive point of the case: another important one is, the alternate morbid excess of action in the serous and the mucous exhalants — a fact often to be noticed in practice, and in the present instance affording a valuable caution against the too free use of astringents in certain hemorrhages.

When the hemorrhage is arrested without any such unfavourable concomitant events, we must endeavour to support the strength of the patient by moderate restoratives, according to the circumstances of the case, and do what we can to obviate the recurrence of hemorrhage by proper regimen, and medicinal treatment directed to the primary disease. This must necessarily vary according to the nature of the case, and it is unnecessary here to enter into the details of the various treatment which may be required in particular cases. The histories related by Portal may furnish some valuable hints if read with due discrimination, and allowance for national peculiarities of opinion and practice. His favourite remedies appear to have been leeches to the anus, and a course of very gentle alteratives, such as lime-water with infusion of camomile, of taraxacum, and other cichoraceæ, pills composed of soap and bitter extracts, clysters, tepid bathing; and in cases where a more tonic treatment was indicated, he prescribed the waters of Vichi, (a saline chalybeate highly impregnated with carbonic acid gas,) cinchona, and the moderate use of sound wine. In old and feeble persons especially, he found the best effects to result from the employment of the two last mentioned articles.

GEORGE GOLDIE.

MELANCHOLIA. See INSANITY.

MELANOSIS, from *μέλας*, *black*, and *νόσος*, *disease*. — Syn. Melanoma; [black cancer, black tubercle;] tumeurs mélaniques; dégénérescence noire; cancer noire; cancer mélané.

The term melanosis is employed to designate a morbid product, the distinctive character of which consists in a dark brown or black colour, of various degrees of intensity.

Although there can be no doubt that many of the ancient physicians were aware of the existence of the disease,—at least in some of its forms, which we are about to describe,—there is no such description of it in their writings as would lead us to believe that they regarded it either as a distinct disease, or in any other point of view than as one of the many local or general morbid states, which they supposed to originate in the predominance of one of the four elements—the *atrabilis* —of their humoral pathology.

The first account of this disease (the discovery of which is claimed by Dupuytren) was given by Laennec, in the Bulletins de la Faculté de Médecine de Paris, in 1806, and it was then named by him mélanose.

This distinguished pathologist describes melanosis as an accidental product, possessing a degree of consistence equal to that of the lymphatic glands, a deep black colour, a homogeneous tissue, somewhat humid, opaque, and presenting an appearance similar to that of the tissue of the bronchial glands of the adult. He says that it afterwards becomes soft, when there oozes out from it, on pressure, a yellowish red, thin fluid, mixed with small black particles, which are sometimes firm, at others friable, but still presenting a certain degree of flaccidity to the touch. At a more advanced period of this softening process, the particles, and soon afterwards the remainder of the mass of which they form a part, becomes quite friable, and is converted into a kind of liquid pulp.

The same author regards melanosis as occurring under the four following forms: viz., 1, that of masses enclosed in cysts (*Mélanoses enkystées*); 2, that of masses without cysts (*mélanoses non enkystées*); 3, that of infiltration in the tissue of organs; 4, that of deposition on the surface of organs.

A *liquid* form of melanosis (which is, in fact, the fourth kind of Laennec) has since been admitted by pathologists. Laennec not only knew of the existence of the disease under this form, but has even described it, although he has not given it a place among what he conceived to be

the essential forms of the disease. This circumstance, which some may consider as an oversight on the part of Laennec, is obviously to be referred to a fundamental error in the pathological doctrines which he maintained regarding the mode of formation, development, and termination of accidental or new products; for he believed that all these products possessed at first a greater or less degree of density, to which state he gave the name of *crudity;* and that they afterwards undergo at some period or other of their existence, by means of some change taking place within themselves, a process of solution, which he describes as the period or state of *softening*. The idea, therefore, of melanosis existing *primarily* in a *fluid* form was repugnant to such doctrines; consequently this form of the disease could not be admitted by him into the class of accidental tissues, to which he conceived melanosis to belong.

The division of melanosis, as to its forms, established by Laennec, has been adopted, with some slight modifications, by almost every author of note who has treated of this subject. The results of more recent researches, however, on melanosis and other morbid states and products which present the same distinctive physical character as the former, seem to us to suggest the necessity of a different arrangement of melanotic formations, and to warrant us in proposing one, which, we think, will comprehend all the forms and conditions under which these formations have been observed to occur.

Melanotic formations may take place in various and different parts of the body; may present considerable variety in the forms which they assume; and may owe their production to the operation of very different agents.

These circumstances do not appear to have been well understood, or their importance sufficiently appreciated, as Laennec has confined his description of melanosis to one kind only of black deposit; whilst Breschet,* Heusinger,† Noack,‡ Andral,§ and many others, have included under the same general denomination various and very different morbid states and products, because of their presenting, as their most remarkable character, a greater or less degree of blackness. To reject every black discoloration or product which does not agree in all its characters with those assigned to melanosis by Laennec, or to collect them indiscriminately into one entire group under the same appellation, as has been done by others, would obviously render the pathology of melanotic formations equally incomplete and inaccurate.

In order to conciliate these differences, and at the same time to facilitate the study of melanotic formations, we shall consider the latter as susceptible of being grouped under two heads, each presenting a certain number of forms, the distinctive or pathognomonic characters of which are derived from some peculiarity of seat, origin, or nature.

In accordance with this plan, we shall comprehend all anormal black substances, fluid or solid, found in the body, under the general title of *melanotic formations*. When these formations depend (as is the case with several of them) on some change taking place in the economy, or the important function of secretion, independently of at least the direct influence of any external cause; or, in other words, when they constitute what is called an idiopathic disease, we shall consider them as belonging to the first head, and as deserving the name of *true melanosis*.

Other melanotic formations have quite another origin, being the consequence of the accumulation of a black material introduced into the body from without; the action of chemical agents; and the stagnation of the blood. These we propose to include under the title of *spurious melanosis*.

We are perfectly aware that these terms are inaccurate, and that to avoid the ambiguity which the use of them may create, we might have arranged all black products or deposits under the general head of melanotic formations, distinguishing each kind in reference to some peculiarity in its external form, origin, or mode of production. By doing so, however, we should not have drawn a sufficiently marked line of separation between these anormal products, which, as we have already said, differ in their nature, and offer only one common external character by means of which they can be recognised by the practical pathologist.

The following tabular view will show at once the nature of the arrangement which we have adopted:

Classification of melanotic formations.

I. TRUE MELANOSIS.

Origin.	A modification of secretion.
Locality.	1. Tissues, systems, and organs. *a*, in the substance and on the surface of organs. *b*, in the cavities of hollow organs. 2. New formations.
Form.	1. Punctiform. 2. Tuberiform. 3. Stratiform. 4. Liquiform.
Seat.	1. Molecular structure of organs. 2. The blood.

II. SPURIOUS MELANOSIS.

Origin.	A. Introduction of carbonaceous matter. B. Action of chemical agents. C. Stagnation of the blood.
Locality.	Of first kind: the lungs. Of second kind: the digestive organs; the surface of serous and mucous membranes; the cavities of hollow organs; new formations. Of third kind: the blood.
Form.	Of first kind: uniform. Of second kind: 1. punctiform; 2. ramiform; 3. stratiform; 4 liquiform. Of third kind: punctiform and ramiform.

* Considérations sur une Altération Organique appelée dégénérescence noire, mélanose, &c., Paris, 1821; Journal de Phys. Exper. tom. i. i, No. 4.

† Untersuchungen über die anomahlie Kohlen; und Pigmentbildung. Eisenbach, 1823; Archives Gén. de Medecine, t. v.

‡ Précis d'Anatomie Pathologique, t. i.; Dictionnaire de Médecine, t. xviii. art. Mélanose.

§ Comment. de Melan. cum in Homin. tum in equis obveniente, &c. 4to., c. trib. tab. æn. Lips. 1826.

Seat. 1. The blood, contained in its proper vessels, or effused.
2. Pulmonary tissue: cellular and membranous.

From a very cursory view of the several circumstances included in the above arrangement, it will readily be perceived that melanotic formations must differ very materially from each other both in their composition and conformation.

I.—True Melanosis.

Locality of the Disease.—The cellular and adipose tissues are much more frequently found to present the true melanotic deposit than any other tissue of the body. Here, also, the quantity of the deposit is infinitely greater than in any other texture, and is always in proportion either to the quantity of this tissue, considered as a simple element, or as a component part of organs; or to the facility with which it admits, from its situation, of mechanical distension. Hence the reason why the largest masses of melanotic deposit have been found in the retro-peritoneal cellular and adipose tissues.

It is also of importance to know that melanosis may occur in either of these tissues separately. Marked examples of it, confined to the *cellular* tissue, are common in various parts of the body; and the most striking example of its circumscribed existence in *adipose* tissue is observed in the appendiculæ epiploicæ, or the fatty appendices of the colon, these bodies being sometimes converted into a homogeneous solid mass of melanotic matter.

Occurring, besides, as a primary affection of these tissues, the melanotic matter frequently extends to those situated in the immediate vicinity of the former, which it penetrates, or in which it forms excavations of various sizes, on account of the compression and subsequent absorption to which they have been subjected during the progressive development of this morbid product.

It is also by means of the cellular tissue that melanotic tumours spread to a great extent along the course of the blood-vessels and nerves, between the folds of the mesentery, and in the cavity of the pelvis, and where, on account of the size which they attain, they sometimes give rise to very serious consequences, to which we shall more particularly allude hereafter.

Mucous Membranes.—The melanotic deposit, notwithstanding what has been said to the contrary, has very rarely been observed in mucous tissue. We ourselves have only met with one example of it in this tissue, and it was even doubtful whether the deposit had its origin in the mucous or submucous tissue, both of them being simultaneously and contiguously affected.

Skin.—An opposite opinion has been entertained regarding the production of melanosis in this tissue, viz. that when found in the skin, it was to be regarded as the extension of that which existed at the same time in the subjacent cellular or adipose tissues. Such is frequently the source of melanosis of the skin; but we have found it to exist as a primary affection of this tissue, particularly in the horse. In this animal the melanotic matter may be seen occupying the very centre of the *cutis vera* in the form of black points, or varying from the size of a hemp-seed to that of a large pea, whether the subjacent textures contain any of the black deposit or not.

Muscular, arterial, and venous tissues; serous and synovial membranes; aponeurosis, tendon, and cartilage.—These have not, so far as we are aware, been found to contain any trace of the melanotic deposit as a primary disease. All of them may present the dark brown or black colour of melanosis, but this arises from contiguity, the imbibition or infiltration of the black matter when in a state of fluidity, or from other causes of a very opposite kind, to which we shall particularly direct the attention of the reader in a subsequent part of this article.

Bone.—The bones are not often affected with melanosis; the spongy bones, as the sternum, more frequently than others.

Liver.—Of all the *compound tissues* or organs the liver is by far the most frequently affected with melanosis: in this respect it is inferior only to the cellular and adipose tissues. The frequent occurrence of the disease, as well as the extent to which it proceeds in this organ, are no doubt in great measure to be attributed to the predominance of the cellulo-vascular element which enters into its composition. We shall, however, endeavour to show that the melanotic deposit is not confined to this element, but that it invades, as a primary formation, the molecular structure of this organ.

Lungs.—Notwithstanding the supposed frequency of melanosis in the lungs, it is by no means so often observed in this organ as in the liver; nor, perhaps, does it ever acquire the same extent as in the latter, although we are aware that cases have been recorded of the whole of both lungs being filled with it. This form of the disease will be considered under *spurious melanosis*, to which division of our subject we conceive it ought to be referred.

Brain.—Few cases of true melanosis of this organ are recorded by pathologists. We have only met with one case, the particulars of which will be related when we come to consider the physical and other characters of melanotic formations. Dr. Hooper (The Morbid Anatomy of the Human Brain, pl. xii. figs. 2 and 3) has represented a case of true melanosis of the brain.

Melanosis of the *kidney* has been occasionally met with. It is also found in the *testes* and *ovaries*; and Andral says that it occurs in the *uterus*. It has also been seen in the *breast*.

The *pancreas* and *lymphatic glands* in several parts of the body, and the *thyroid* and *parotid glands*, have presented the disease in various forms.

Melanosis of the *eye* has been frequently observed by surgeons, either alone, or combined with other morbid products.

Examples of melanosis occurring in the cavities of serous and mucous membranes are given by various authors; and Breschet, Cruveilhier, and Andral, have described it as existing within the veins. We have also had occasion to observe it in these cavities; but it is the spurious melanosis which has, in general, been observed in these situations, and has been described as examples of the true kind.

Blood.—The presence of true melanotic matter in the blood is an important fact, and one which,

under favourable circumstances, may be easily ascertained.

It has chiefly been in the minute veins of the liver that we have observed melanosis as a primary formation in the blood. The vessels which, in this organ, contain the melanotic matter, appear like black lines, striæ, or dots, and sometimes in a pencillated form, all of which appearances may be recognised as originating in the ultimate extremities of the veins of the liver, most probably the hepatic.

We are not disposed to believe that the black ramiform appearance so frequently seen in the lungs is owing to the presence of true melanotic matter in the extreme branches of the veins. Such may sometimes be the case, although we have not been able to satisfy ourselves that it really is so. The black colour of the contents of these vessels we rather attribute to the simple stagnation of the blood, and to the subsequent removal of *that*, the production of the red colour. A similar vascular arrangement of black matter has also been seen in the vessels of the stomach, and described as melanosis by several pathologists. But in this case error is conspicuous. The writer of this article has shown in another publication* that the black colour of the blood, not unfrequently seen in the vessels of the stomach, in the cavity of this organ, and in that of the intestines, is the result of a chemical process, and is always observed when the blood in these parts is either directly or indirectly brought in contact with the acid products which they contain: melanotic formations of this kind naturally take their place among those of spurious melanosis.

The existence of the matter of melanosis in the blood accounts satisfactorily for its being sometimes met with in the cavities of some secreting organs. It is also said to have been found in the saliva and bile, and likewise in the sweat and urine, in which last fluid a dark colouring matter was found by Dr. Marcet, which has received the name of *melanic acid*. The presence of melanotic matter in these secretions does not, however, appear to us to have been proved, except in the serous and mucous. It has, however, been observed in the medulla of bones, and in the humours of the eye.

Melanotic fluid may be found in cavities, either natural or accidental, without its being the product of their secretion. This happens when melanotic tumours perforate the walls of these cavities, and pour their fluid contents into them. This we have observed in the thorax and abdomen; and in one case a melanotic tumour had perforated the right lateral ventricle of the brain, in which was found a considerable quantity of black fluid, which afterwards passed into the third and fourth ventricles, and thence into the theca vertebralis. Such also is, in general, the source of the melanotic fluid found in accidental cavities.

The production of melanosis, scirrhus, carcinoma, and encephaloid formations in the same organ, and even in the same diseased mass, is occasionally met with.

The simultaneous existence of melanosis with these diseases, and the real or supposed analogy which the former presents in regard to its mode of development, progress, and termination, when compared with the latter, have induced some pathologists to consider melanosis as a species of cancer: how far this opinion is founded in truth, we shall not at present stop to inquire.

Such is, we believe, a correct, though general statement of the topography of melanosis. We shall now endeavour to describe the various forms which it assumes in the different tissues, systems, and organs of the body.

Of the Forms of True Melanosis.

1. *Punctiform Melanosis.*—Of the four forms under which we have included the true melanotic deposit, the first is that in which the black colouring matter appears in minute points or dots, grouped together in a small space, or scattered irregularly over a considerable extent of surface, and which we have termed *punctiform*. These appearances are most frequently met with in the liver. The cut surface of this organ appears as if it had been dusted over with soot or charcoal powder. When examined by the aid of a lens, the black points sometimes present a stellated or pencillated arrangement, which in some cases can be distinctly seen to originate in the ramiform expansion of a minute vein filled with black matter. At other times the melanotic matter appears to be deposited in the molecular structure of the organ in a manner similar to that of the organizable part of the blood. In such cases it consists of the most minute points disseminated throughout the acini or little lobules of the liver, and which then assume a uniform grey aspect. The various shades of grey and black which the liver presents when thus affected, depend on the greater or less quantity of the black punctiform injection; and we are inclined to believe that the melanotic tumour in this organ has, sometimes, a similar origin. We have always found the two forms, the punctiform and tuberiform, combined in the liver, lungs, and also the kidney. The "*infiltration des organes par la matière des mélanoses*" of Laennec is, in many instances, owing to the punctiform dissemination of the melanotic matter. In others it is obviously produced, as Laennec believed, by the simple diffusion of the liquid black matter throughout the tissues of an organ more or less remote from the part where it was formed. It is likewise to be attributed to general venous capillary congestion, or the effusion of blood, and the subsequent changes which this fluid undergoes, to be mentioned hereafter.

Punctiform melanosis is not observed in the brain, cellular, adipose, serous, and fibrous tissues It may take place in mucous membranes; but its occurrence must be rare, as we have already said that we have only seen one case of melanosis of this tissue, in which the submucous tissue was affected at the same time.

2. *Tuberiform Melanosis.*—This is by far the most common of all the forms of melanosis. The bulk of the melanotic tumour varies greatly, and, as we have already said, always acquires its maximum in loose cellular and adipose tissues: sometimes not larger than a pin's head, at others it equals in bulk the head of a child, or even that

* Recherches sur la Dissolution Chimique ou Digestion des parois de l'Estomac après la mort, &c. Journal Hebdomadaire de Médecine, 1830. No. 87, p. 351. No. 91, p. 517.

of an adult. It is, however, only in the horse that it acquires such an extraordinary size; in man it is seldom larger than an orange.

The great size of melanotic tumours depends on the agglomeration of smaller ones, the number of which varies with the size of the aggregated mass, or with that of the individual tumours of which it is composed.

The melanotic tumour, when single, is always of a spheroidal or ovoid form; and when aggregated, presents a lobulated appearance. In compound tissues or organs it is more frequently found single; in the cellular and adipose tissues, aggregated.

In both of these forms it has been described as encysted and non-encysted. It is said to be encysted when contained in a membranous capsule, and non-encysted when it lies in immediate contact with the tissue of the organ in which it is seated.

The encysted melanotic tumour does not, so far as our observation extends, occur, unless in a very imperfect state, in any of the compound tissues. It is chiefly found in the cellular and adipose tissues, a circumstance which the nature of the tissues sufficiently explains. The cyst of the tumour consists of cellular membrane—not of new formation—stretched out in the form of a thin transparent covering, from the gradual accumulation of the black melanotic matter contained within it. Hence melanotic tumours of the latter tissues are always provided with an external covering, which, as it not only adheres closely to them, but generally forms a constituent part of their internal arrangement, is separated from the loose surrounding cellular tissues when these tumours are removed, and which are therefore said to be contained in a cyst.

The tuberiform arrangement of the melanotic matter contained within a cyst is not confined to the cellular tissue as a simple element, or to those organs in which this tissue is more or less abundant. We have found it on the surface of the pleura and peritoneum in man, (Transactions of the Medico-Chirurgical Society of Edin. vol. i. p. 279, and Edin. Med. and Surg. Journal. vol. xxvii. p. 151,) and also in the horse. In this situation the melanotic tumours frequently assume a pedunculated appearance, being suspended by a slender neck, like some polypi, and are covered by a thin transparent serous membrane. Under such circumstances it is often difficult to determine whether the serous covering of these tumours is a new product, or merely an extension of pleura or peritoneum produced by the gradual accumulation of the melanotic matter in the cellular tissue beneath these membranes; and the difficulty of the case is increased if there exist at the same time, and in the same organ, tumours of a similar nature either in the sub-serous cellular tissue or in the parenchyma which it covers. Instances, however, have occurred which have afforded us the means of determining the seat of these extra-pleural and extra-peritoneal melanotic tumours. Thus we have seen these tumours co-existing with the more simple forms of the melanotic deposit, such as striæ or patches, consisting of a fluid or semi-concrete black matter lying on the free surface of the pleura or peritoneum, and enclosed in a fine, loose, spongy tissue, or serous covering of considerable tenacity, although almost equal in tenuity to a spider's web. The pleura and peritoneum beneath the melanotic deposit were perfectly entire, and therefore the solid material, whether cellular or serous tissue, in which it was enclosed, must be regarded as a new formation. The inference which we would draw from this is, that the melanotic tumour may, in some instances, have a similar origin, viz. in the deposition of melanotic matter on the surface of the serous membranes, and the subsequent or simultaneous formation of a tissue, which afterwards acquires the solidity and characters of a general serous envelope.

Melanotic tumours of the pleura pulmonalis and costalis are found either solitary or aggregated in considerable number, and vary in bulk from the size of a pea or less, to that of a cherry. When they are found in the peritoneum, it is generally where this membrane receives the name of epiploon.

4. *Stratiform Melanosis.* — This form of the melanotic deposit occurs only in serous surfaces: it presents two degrees or stages. In the first the black matter is so sparing in quantity that the serous membrane on which it is deposited presents an appearance as if it had been painted with ink or stained with a deep brown or black colour. In the second the black deposit is more copious, forms a distinct layer on the surface of the serous membrane, above which it is seen to project. The consistence of the matter thus deposited resembles, in general, that of firm jelly, and is enclosed, as we have already said when speaking of the preceding form of melanosis, either in a soft spongy tissue, or fine transparent serous membrane of new formation; so that, when pressed, it feels pulpy, but is not removed by a scalpel being passed over it, unless some force is employed.

This form of melanosis is described by Andral and others as occurring frequently on the peritoneum in chronic peritonitis. Such, however, is not the case. The "*melanoses déposées sous forme de couches solides à la surface des membranes*," described by this author, is of a diametrically opposite nature to that which we are now discussing under the appellation of the *stratiform*. It is the result of the chemical action of certain fluids and gases, formed in general in the digestive organs, on the blood contained in the vessels of the pseudo-membranes of the peritoneum, or effused into the substance of the one, or on the surface of the other, as we shall endeavour to demonstrate when we come to treat of this mode of production of melanotic formations.

The stratiform melanosis of serous membranes has not been observed to any extent in man. In the horse it is sometimes considerable in degree and extent, and is chiefly found on the peritoneum, pleuræ, and pericardium.

4. *Liquiform Melanosis.*—The appearance of melanosis in a liquid form has in general been confined to natural or accidental cavities into which it has been supposed to be poured by a process somewhat analogous to that of secretion. This is certainly one of the modes to which its presence in these situations is to be attributed; but it is also owing, as we have already remarked, to the effu-

sion of the same substance during the softening process of melanotic tumours; and it may also be observed that some of these tumours, when encysted, are found to be composed entirely of the black fluid or semi-fluid matter of melanosis. We shall, however, confine our description of the liquid form of melanosis as it occurs in natural or accidental cavities.

Among the former, the cavities of the pleura and peritoneum furnish almost the only examples in which liquid melanosis has been observed, and that, too, in very small quantity. We have never seen it in man, and rarely in the horse.

The mucous cavities, particularly in the stomach and intestines, are mentioned by several pathologists as furnishing, not unfrequently, examples of the presence of melanosis under this form. But in this instance, as in those to which we have already more than once alluded, in which other forms of melanosis are supposed to have their seat in the mucous tissue itself, the same mistake has been committed: the blood, either effused into these cavities or contained in the vessels of their proper tissue, and having been submitted to the influence of an external chemical agent, being in general the *material* thus improperly denominated.

As an example of accidental cavities in which fluid melanosis has been found, we may mention the serous cysts which form in the ovaries, and the capsules of the ova which have escaped from these bodies.

Whatever form the melanotic deposit may assume, it is never, so far as we know, confined to one tissue or organ only; on the contrary, it is found to pervade a greater or less number of these simultaneously or successively; being, in some cases, equally extensive every where; in others, small in quantity in one organ, while in another it is so abundant, that hardly any of the natural texture is to be perceived. The tuberiform deposit is the most conspicuous and prevalent of all the forms which this morbid product assumes.

General Characters of Melanosis.

1. *Physical Characters.*—These comprehend chiefly the colour, bulk, and consistence of the several forms of melanosis which we have described.

The *colour* of melanosis, whether in the solid or fluid state, although always tending to black, frequently presents various shades of brown, such as that of bistre or China ink, having either the dull aspect of soot, or the glossiness of pitch. The black colour and glossy aspect is more frequently met with in inferior animals than in man; and in both, these appearances are most marked when the melanotic deposit exists in the form of a firm tumour. It is hardly necessary to observe that the quantity of cellular tissue intermixed with the melanotic matter, as well as the presence of a certain quantity of blood, give rise to a greater variety in the shade and depth of colour than this substance would otherwise present.

The *bulk* which the melanotic deposit may acquire is sometimes very considerable even in the human species. It may form irregular or lobulated masses in the cellular tissue as large or larger than the fist; and in parenchymatous organs, such as the liver, it acquires the bulk of a hen's egg, or even that of a small orange. In the cellular tissue, the larger masses are almost always produced by the union of smaller ones, although in one instance we found in this situation a single tumour as large as a hen's egg. In the liver, single tumours of a large size are more common than in any other of the compound tissues, or even the cellular tissue, for the reasons which we have already stated. In the horse, the aggregated melanotic tumour has sometimes been found to weigh from twenty to thirty, and even forty pounds.

The *consistence* of melanosis, as we have already seen, presents great variety: there are two circumstances which seem to determine the degree of consistence which it is found to present when examined *in situ*: these are the *texture* and the *form* of the part in which the deposit takes place. Thus it is never found solid in large cavities, such as the abdominal and thoracic, for the plain reason that its diffusion is not limited by dense unyielding tissues. Even in tumours attached to the serous covering of these cavities, it is found for the same reason either perfectly fluid or not more dense than animal jelly. In loose cellular tissue, too, one, two, or a limited number of cells, more or less distended into the form of small tumours, are occasionally found to contain the black matter in a fluid state. In the dense texture of the cutis, on the contrary, even the smallest tumours may be nearly as hard as cartilage, and are generally as firm as the pancreas. In the lymphatic glands, and in the brain, the melanotic tumour acquires only a medium degree of consistence, although it is generally firmer in the former than in the latter, on account of the capsule of the glands acting as a compressing cause. In the liver and lungs we perceive the same relation between the structure of these organs and the consistence of the melanotic tumours formed in them. In both they are pretty firm; much about the consistence of a lymphatic gland; from the black matter being contained either in the capillaries, molecular structure, or cellular texture of these organs.

It is an important fact that the conditions of texture and form, or the composition and conformation of the tissue or organ in which the melanotic deposit takes place, determine almost exclusively the degree of consistence which this morbid product, and indeed every other, presents when examined *in situ*. That absorption and imbibition exercise a certain influence in modifying, under certain circumstances, the consistence of this matter, cannot be doubted, inasmuch as they are known to give rise to very marked changes in the consistence of some other morbid products. We have, however, already shown that the operation of either of these modifying causes, as regards the consistence of melanosis, must be very limited, since there is always a direct relation between the consistence of this morbid product and the conditions of the tissues which we have named, in which it is received and retained. It is indeed from a knowledge of this pathological fact that we are led to believe that the *primary* condition of melanosis is that of a fluid, formed or collected in the capillaries and minute cellular areolæ, or combined with the solid or fluid elements of the body. If this fact is not admitted to be demonstrated by the evidence which we have adduced, we should then be compelled to adopt,

at least in part, the opinion of Laennec, namely, that melanosis is, *ab origine*, a solid accidental product: as to its being a *tissue*, as it was believed or said to be by the same author, we shall inquire by-and-by, when speaking of its anatomical characters. And to show that this mode of origin is not peculiar to melanosis, we may mention that tubercle, cancer, and every other morbid product can be traced to this their primary and fluid state of formation. In this respect, therefore, there is no difference between morbid and natural products. The law is the same in both: the hardest texture, in the latter, namely, bone, being in its primitive state a mere jelly, as scirrhous and accidental bony formations are in the former. Even calculi do not form an exception to this law, the bile, urine, and other fluids, in a morbid state, constituting the primary forms of these bodies, before their respective elements become tangible to our senses by means of chemical agency; and as the last link in this chain of analogy, the blood—the *fons et origo vitæ*—may be regarded as the representative of the primary condition of organization in general.

Like all colouring matters in a fluid state, that of melanosis, when placed in contact with a white surface, communicates to it its peculiar tint, but the stain thus produced is readily removed by ablution. In its natural state, or when mixed with water, exposed to the air it becomes dry, brittle, and pulverizable, and does not emit the odour of putrefaction until after a long period. When burnt, it swells, gives out a great deal of smoke, a marked empyreumatic odour, and is converted into a carbonaceous substance. It is quite opaque, and has no marked odour or taste.

2. *Anatomical Characters of Melanosis.*—Several of the anatomical characters of melanosis have already been enumerated in the description which we have given in the different forms of this disease. When speaking of what is called the *encysted* melanosis, we explained the reason why this appellation had been employed, namely, that the single or aggregated masses of melanotic matter found in the cellular tissue are enclosed in and united together by a capsule of the same tissue stretched out by the gradual accumulation of this matter. This membranous covering (for it is not a cyst) is generally so thin and transparent, that the black colour of the melanotic matter is hardly if at all obscured by it. If the tumour be simple, and a quantity of the black deposit has been washed out of it, a multitude of fine filaments and lamellæ are seen connected with the membranous covering of the tumour, traversing the substance of the latter in every direction, and presenting an appearance resembling cellular tissue when distended with serosity. When a number of tumours are united into one mass, they are included in a common capsule, and separated from one another by their respective coverings and portions of cellular tissue contained in the angular spaces sometimes left between them.

It is in these filamentous and cellular tissues alone, which are obviously not of new formation, that blood-vessels or nerves are to be seen. Minute arteries and veins can be seen ramifying in both, although they are rarely numerous, and we have never seen them pass beyond the limits of these tissues. Large branches and even trunks of arteries, veins, and nerves are sometimes found passing over the surface, or included in the aggregated masses of melanotic tumours.

There is a considerable difference as to the relative quantity of cellular tissue and melanotic deposit which constitute these tumours, when examined in man and in inferior animals. We have never found the melanotic tumour in the horse to contain much cellular tissue: indeed, it is sometimes impossible to detect its presence until after the tumour has been macerated and the black matter squeezed out, when there is found to remain a small quantity of extremely fine, soft, cellular tissue. In man, on the contrary, we have seen it at least equal in quantity to the black matter in tumours nearly as large as a goose's egg formed in the subcutaneous cellular tissue. An example of this kind of melanotic tumour, which we had an opportunity of examining in the recent state, is now preserved in the museum of the Royal College of Surgeons in Edinburgh, and a drawing of it is in the possession of Dr. Thomson, the distinguished Professor of Pathology in the university of that city. The cellular tissue was remarkably conspicuous, in some points almost as dense as fibrous tissue, formed bundles which intersected one another in various directions, and thus formed irregular cells of various dimensions, in which the melanotic deposit, of the consistence of fluid pitch, but without tenacity, was contained.

We have stated that the blood-vessels are confined in their distribution to the cellular tissue, which enters into the composition of melanotic tumours, and that they are never seen to penetrate the black deposit. There is, however, one kind of tumour, already alluded to, which is almost entirely formed of blood-vessels and a black or deep brown fluid. We formerly expressed a doubt whether this tumour should be regarded as one of the true melanotic kind, by reason of its anatomical composition being an exception to that observed in all others. This kind of tumour we have only met with once, and so far as we know there is only one other example of a similar kind on record. The subject of our case was an old man, between seventy and eighty years of age, brought to the Hôtel Dieu of Paris in a state of incomplete paralysis, and incapable of giving any account of himself. He lived several days; had little or no fever or excitement of any kind. The paralysis soon became complete and general, and he died in a state of collapse and profound stupor. On examining the body after death, black or deep brown coloured tumours, two of which were as large as a hen's egg, occupied both hemispheres of the brain. One of them had made its way through the walls of the right lateral ventricle, poured a quantity of the black fluid with which it was impregnated into this cavity, which had passed from thence into the opposite ventricle, the third and fourth, and along the spinal cord to its inferior extremity. Although these tumours were almost entirely surrounded by the medullary substance, they must have been seated originally on the external surface of the brain between the convolutions; for they were intimately connected with the pia mater, the blood-vessels of which constituted by far the greater part of their bulk

The blood-vessels were crowded together in parallel bundles at their exit from the pia mater, became tortuous in the substance of the tumours, some of them having nearly a line in diameter; were reflected backwards at their extremities in the form of irregular interlaced groups, towards which two or three small arteries coming from the pia mater were seen to distribute themselves. The black colouring matter of these tumours was very abundant, nearly as fluid as ink, and was contained not only in the loose cellular tissue which separated the blood-vessels from one another, but likewise in the vessels themselves. The veins (or large tortuous vessels described above) were completely filled with it, whilst the arteries, minute as they were, were distinctly seen to carry red blood. The medullary substance was slightly reddened and somewhat soft where it was in contact with one of the large tumours only. The cortical substance of the convolutions contained three or four melanotic tumours rather larger than hemp-seed. They were quite unconnected with the pia mater, were not composed of blood-vessels like the others, presented the usual consistence of melanosis, and contained but a minute quantity of cellular tissue.

Besides these black tumours — vascular and non-vascular — there was one of another kind, about the size of a small cherry, situated in the brown substance of the corpus striatum of the right hemisphere. Instead of being black, it was of a reddish grey colour, and was traversed by a great many minute vessels filled with red blood. It was nearly of the same consistence as the others, but, when pressed, discharged a small quantity of a milky or creamy looking fluid. After having been submitted for some time to ablution and gentle pressure, it assumed an appearance somewhat similar to that observed in the black vascular tumours: its tissue was of a spongy reticulated character, of a dull red colour, and vascular. There was no tumour of a similar kind in any other organ of the body; but as it participated in the characters of erectile and carcinomatous formations, we may mention at present that there existed a somewhat analogous disease of the right parotid gland. This body formed a large oblong tumour, composed of a substance partly of a scirrhous and partly of a mammary aspect and consistence, grouped into irregular masses of various sizes, surrounded by a considerable degree of ecchymosis. At its upper extremity and on a level with the ear there was a melanotic tumour of a firm consistence and homogeneous aspect, as large as a Spanish nut. This tumour had perforated the external auditory canal, and projected into its interior.

Black tumours, similar to those of the brain, were also found in the abdominal viscera. The duodenum contained one, the ileum five, and the epiploon one. In the intestines they appeared to be seated in the submucous cellular tissue, and formed the bottoms of black ragged ulcers occupying the mucous membrane. They were of a round or oval shape, flat, the largest of them about an inch in diameter. The one found in the epiploon was nearly as large as a walnut. It was attached to one of the prolongations of this covering, between which and the tumour there existed the same kind of vascular connection as between the pia mater and some of the tumours in the brain: it presented likewise the same internal structure as the latter. Those which were found in the submucous cellular tissue did not present any peculiarity of structure.

The above description contains the most of the anatomical facts of any importance connected with this interesting case, which occurred under the care of Dr. Menière, while *interne* in the Hôtel Dieu, and to whom we feel much indebted for the opportunity he afforded us of examining and delineating the appearances we have described. When shown to Baron Dupuytren, he pronounced the case to be one of melanosis; or, in his own language, *cancer noire;* his opinion being obviously founded on the *colour* of the tumours, without any regard to their *structure.*

Dr. Menière, on the contrary, who has had extensive opportunities of examining diseased structures, considered it to be a case of fungus hæmatodes, the vascular organization of the tumours constituting, according to him, the essential character of the disease; whilst the black colour was merely an accidental circumstance of very inferior importance. We ourselves are of opinion that neither of these notions is borne out by the anatomical facts of the case as above related; and had we not already extended this part of our article beyond the limits usually assigned to descriptive details in a work of a practical nature, we should have furnished collateral evidence sufficient to show that both opinions are exclusive, incomplete, and inaccurate. We shall, therefore, only make a few remarks, with a view to our being justified in placing for the present this case in the division of *true melanosis.* And first, we have two or three melanotic tumours of the ordinary kind in the cortical substance of the brain; one in the parotid, or in a carcinomatous tumour found in that gland; to which we may add those of the intestines; we have here, therefore, as far as regards these tumours, a case of true melanosis. Secondly, there existed a large tumour behind the ear and in the parotid, presenting the most marked characters of scirrhus and cancer. Here, then, we have a case of cancer, but not of fungus hæmatodes. Thirdly, we have the black vascular tumours of the brain. The question is—did they present the anatomical characters of scirrhus, cancer, or fungus hæmatodes? Certainly not. They were no doubt vascular, but must not on that account be identified with carcinoma or fungus hæmatodes, for the essential character of both of these was wanting, viz. a fluid resembling milk or cream, or a substance of the colour and consistence of brain; and, besides, carcinoma and fungus hæmatodes do not necessarily possess a high degree of vascular organization.

The production of the black vascular tumours of the brain may be accounted for as follows. The original state of these tumours we believe to have been the same as that of the small tumour situated in the corpus striatum, and which, we said, was of a compound nature, from its structure resembling that of erectile tumours, and the fluid it contained being similar to that which is found in carcinomatous tissue. The melanotic

fluid, which we found deposited in the usual way, that is to say, in the form of small, dense, homogeneous tumours, in several points of the brain and elsewhere, appears also to have been deposited in these erecto-carcinomatous tumours, after they had acquired considerable bulk. Thus the black fluid which they contained, (which we have no reason for believing differed in any respect from that contained in those that were not vascular,) instead of being deposited in the form of a homogeneous mass, assumed the form and arrangement of the anatomical elements of these tumours, that is to say, was collected in the veins and cellular tissue of which they were composed. From these remarks on the origin and mode of production of the black vascular tumours of the brain, we do not hesitate to say that, in the strict sense of the term, they do not merit the appellation of true melanotic tumours, but that they ought to be considered as examples of melanosis taking place in a tissue of new formation, just as it is found to do in other tissues, whether healthy or diseased.

The other case of vascular melanosis to which we alluded is mentioned by Lobstein. (Traité d'Anatomie Pathologique, tome premier, p. 461.) The patient was an emaciated old woman, between eighty-five and ninety years of age. The inspection of the body was made by M. Alex. Lauth, and also delineations of the melanotic tumours. Besides melanosis of the spongy substance of the inferior third of the femur, there were several black tumours on the anterior region of the neck, and a large one in the inferior lobe of the right lung. The former appeared to be encysted; they were of a round form, and lobulated; the most of them movable under the skin, and were formed of a plexus of veins coming from the neighbouring veins, which became dilated as they approached the tumours. All these vessels, not only those which penetrated, but also those which formed the tumours, were filled with a deep brown substance, having, from the presence of an irregular filamentous tissue, an appearance of organization. In some of the veins, the substance which filled them adhered firmly to their internal surface, and seemed continuous with their tissue, although the latter differed from the former, from its being firmer and of a whitish colour.

The matter contained in the tumour in the lung was fluid, and as black as ink; it was infiltrated into the pulmonary parenchyma, which was reduced to a filamentous tissue. However, when minutely examined, this tissue was found to be composed of arteries and veins, swimming in the melanotic fluid, and containing a quantity of it in their interior.

Although the author of this observation does not speak of any other morbid product having been found in the body, except a small horny excrescence on the left side of the thorax, we feel satisfied that the vascular tumours which he has described were precisely of the same kind as those of which we have just given a description. The most important circumstance in both cases was the presence of the melanotic matter within the blood-vessels of the tumours. In Lobstein's case, it appears to have been contained in the arteries as well as veins, whilst in ours it was observed only in the latter. In either case, the presence of melanosis in the blood is clearly demonstrated. Venous absorption might be considered by some sufficient to explain its presence in the veins; but it was also found in the arteries; and besides, we have already shown that its existence in the veins of the hepatic tissue is prior to, and independent of, its presence in the cellular tissue, or its combination with the molecular structure of this organ.

3. *Chemical Composition.*—The melanotic deposit in the fluid and solid state has been submitted to very minute chemical analysis in this country and on the continent; the uniform result of which shows that melanosis bears a strong analogy in its composition to that of the blood. The most complete analyses of melanosis that have been published, are those of Lassaigne and Barruel,* in France, and of Dr. Henry, of Manchester. (A case of melanosis, &c., by Thos Fawdington.) We shall not enter into the details of the analysis of the melanotic deposit furnished by each of these able chemists, but shall content ourselves by giving the facts thus elicited, which seem to prove that the composition of this morbid product is very similar to that of the blood; referring the reader for further information to the works mentioned below.

Mons. Lassaigne found the melanotic tumour of the horse composed of — 1st. coloured fibrine; 2d. a black colouring matter soluble in weak sulphuric acid, and in a solution of the subcarbonate of soda, each of which becoming at the same time of a red colour; 3d. a small quantity of albumen; 4th. muriate of soda, subcarbonate of soda, phosphate of lime, and oxide of iron. According to Mons. Barruel, melanosis of the human subject is essentially composed of the colouring matter of the blood, united with fibrine, both of them "*se trouvant dans un état particulier*," and three distinct kinds of fatty matter. The first of these is soluble in alcohol at a moderate temperature, crystallizable; the second soluble in alcohol at a boiling heat only, soft, and not crystallizable; the third fluid at the ordinary temperature of the air, and of a reddish-brown colour. This chemist found also a considerable quantity of the phosphate of lime and iron.

The following is the result of the analysis obtained by Dr. Henry from a portion of a softened melanotic tumour taken from Mr. Fawdington's patient, and after it had been kept some time in spirit:—

1st. By filtering through paper, much of the colouring matter remained on the paper, and the colour of that which passed through was much less intense.

2d. Boiling does not destroy the colour, nor even when a little caustic potash has been added.

3d. It is not changed by acids even when heated, except by nitric acid, which deprives it of its black colour, and turns it yellow.

4th. A stream of chlorine passed through the liquid destroys the colour, and throws down light fawn-coloured flocculi.

5th. A few grains of corrosive sublimate stirred

* Considérations sur une altération organique appelée dégénérescence noire, &c. Par G. Breschet, Chef des travaux anatomiques à la Faculté de Médecine de Paris, &c. &c.

up with the fluid precipitates the whole of the colouring matter, and leaves the supernatant liquid quite clear.

6th and 7th. Nitrate of mercury and muriate of tin produce the same effect, but more slowly. We may also mention that M. Foy (Archives de Médecine, Juin 1828) found in the melanotic tumour of the horse,

Albumen	15,00
Fibrine	6,25
A highly carbonized principle, probably altered cruor	31,40
Water	18,75
Oxide of iron	1,75
Sub-phosphate of lime	8,75
Muriate of potash	5,00
Ditto soda	3,75
Carbonate of soda	2,50
Ditto lime	3,75
Ditto magnesia	1,75
Tartrate of potash	1,75

From the results of all these analyses it is sufficiently obvious that melanosis is essentially composed of the constituent elements of the blood. The colouring material of its composition appears, also, to bear considerable analogy to that of the blood, and is, according to Foy, a highly carbonized principle. Andral puts it as a query, whether the fatty substances found by Barruel belonged to the melanotic tumours analyzed by this chemist, or to the tissues of the organ in which the tumours were formed? That these fatty substances may have become incorporated with the melanotic matter during its deposition is possible; but it must also be admitted that they may have been deposited along with it as constituents of the blood, inasmuch as it has been shown by Lecanu (An. de Chim. et Phar. xlviii. 308) and by Dr. B. Babington, that this fluid always contains in the healthy state a certain quantity of fatty crystalline and oily matter.

Seat, Nature, and Origin of Melanosis.—We must refer the reader to the preceding section for proofs that the material of which melanosis is composed is formed in the blood, and afterwards deposited in the various parts in which it is found. It is not only because this material is seen in the blood that we have fixed its *seat* in this fluid, but because our anatomical researches show that it is there formed. The chemical analysis which we have given of this substance confirms the accuracy of this opinion, by showing that it is essentially composed of the colouring matter of the blood. The separation of this colouring matter, as well as its disposition, in the form of melanosis, must be regarded as the result of a process similar to that of secretion. [M. Al. Cazenave (*Dict. de Méd.* 2de édit. xix. 343, Paris 1839) with MM. Breschet and Barruel, considers it, indeed, both from chemical analysis and an examination of facts, to be nothing more than modified extravasated blood.] Several pathologists in France and Germany regard the carbonaceous matcrial of melanosis as having its origin in a modification of the secretion of the natural pigments of the body, and more especially of that on which the colour of the hair and skin depends. This opinion was first entertained by Gohier, (Mémoires et Observations sur la Chirurgie et la Méd. Vétérinaire, Lyon, 1813, tom. i.,) who states that melanosis probably depends on the increase or diminution of some of the elements which enter into the composition of the body of the white and grey horse or in some remarkable change in the nature of the secreted fluids. The carbon, says this author, which is found in melanosis, is too easily separated by calcination, to permit us to ascribe the colou. of this disease to any other substance. Breschet afterwards pointed out the analogy which exists betwcen the black matter of melanosis and that which colours the choroid, the uvea, the rete mucosum of Malpighi in the negro, and the placenta of certain carnivorous animals. He regarded, also, the colouring matter of several morbid secretions as of a similar nature, such as melæna, the black coating of the tongue in fevers, the fluids rejected by vomiting in yellow fever, &c.—an opinion which we consider to be by no means correct. A similar opinion is, however, entertained by Heusinger in his researches on the accidental production of pigments and carbon in the human body. The following are the deductions which this author gives as the result of his investigations:—1. that all the pigments secreted in the body in the healthy state are rich in carbon: 2. that the accidental pigments resemble the natural; 3. that the anomalous pigments are a modification of the colouring matter of the blood; 4. that their secretion is intimately connected with that of the fat; 5. that they announce the predominance of the venous system, the want of oxidation, and particularly the decarbonization of the blood. Some of these deductions, viz. that the secretion of the colouring matter of melanosis is intimately connected with that of the fat and the predominance of the venous system, do not appear to us to be supported either by the evidence brought forward by the author, or by such facts as have fallen under our own observation; for in the many cases of melanosis which we have seen in man and various kinds of animals, there did not appear to be any visible connection between this disease, either with regard to its locality, degree, and extent, and the secretion of fat, or any state of the venous system in particular. The much greater frequency of melanosis in the grey and white, than in the bay, brown, or black horse, is a circumstance of some importance, and which may be regarded as favourable to the theory which ascribes the origin of melanosis to the accumulation in the blood of the carbon which is naturally employed to colour different parts of the body, and more particularly the hair. This theory we are disposed to adopt, not only as regards the formation of the disease under these circumstances of colour, but also when it occurs in animals of a dark colour, and in man indiscriminately, whatever may be the peculiar tint of the skin or colour of the hair. In the first instance, the colouring matter formed is not deposited in the regular physiological order; in the second it is formed in too great quantity. In both cases its presence and accumulation in the blood are accounted for. Its deposition as an anomalous product in various parts of the body follows, as we have already said, as a consequence of its separation from that fluid by a process of secretion.

Causes.—The above remarks antioipate the

necessity of any further notice on what is called the *proximate causes* of melanosis. With regard to the *remote causes* of this disease, particularly the influence of external agents, it does not appear to us that our knowledge amounts to any thing more than conjecture. We know that the development of colour in general is favoured by exposure to light, heat, and that combination of physical agents which constitutes the climate of warm countries; and that it is retarded by obscurity, cold, imperfect sources of nutrition, &c. None of these facts, however, seem capable of affording us any explanation respecting the remote origin of melanosis, still less of its affecting one kind of animal rather than another. We should have observed before, that melanosis occurs most frequently towards the decline of life.

Progress of Melanosis.—Under this head, it is our intention to describe, 1st, The changes which take place in the melanotic deposit itself; 2d, The changes induced by this deposit in the tissues and organs in which it is contained, or with which it is more or less immediately connected.

1st, *Changes produced in the melanotic deposit.*—Only two changes are observed to take place in the melanotic matter after its deposition. The first consists in the inspissation or solidification, the second in the softening or liquefaction, of the melanotic matter. What we have already said on the various forms, the physical and anatomical characters of melanosis, will in a great measure enable the reader to trace these changes to their respective causes, and to explain the manner in which they are produced. We have, we hope, satisfactorily shown that the material of which melanosis is composed exists primarily in a fluid form, and that every increase of consistence which it afterwards acquires, is owing chiefly either to its combination with the molecular structure, or the dense unyielding nature of the tissues or organs in which it is deposited. In the first instance, (examples of which were pointed out in the liver,) its consistence becomes considerable; in the second, it acquires its maximum of density, of which its development in the cutis vera furnished us with the most striking examples. When retained in the vessels in which it is formed, it either remains in its primitive state of fluidity, (see our case of melanosis of the brain,) or it acquires a certain degree of consistence, (Lobstein's case of melanosis of the neck, &c. l. c.) We also found that when it is effused on the surface of the serous membrane, the degree of consistence which it afterwards acquires depends entirely on the development of an accidental serous or cellular tissue within which it is included. Its various degrees of consistence in cavities, viz. those formed in the cellular tissue by its gradual accumulation, are referable to the same causes; the mechanical resistance offered to its diffusion by the tissues and organs we have named. These facts regarding the manner in which the solidification of the melanotic matter is effected, as well as the causes to which it is to be referred, appear to us so conclusive, that it would serve no good purpose were we to call in the evidence of analogy furnished us by the mode of development of other products of a similar and dissimilar kind, as farther proof of the accuracy of the opinion which we have just expressed.

From these facts it follows as a consequence, that the process of softening cannot take place until that of solidification has been at least carried to a certain extent: perhaps it never does take place until it has been carried to its maximum. For the softening of the melanotic deposit is observed only when it has acquired the form of a tumour, or occupies an irregular portion of an organ. Under these circumstances, the softening of the hardened melanotic mass is effected in the two following ways: first, by the destruction of the tissues included within it and around it; second, by the effusion of serosity caused by its stimulating power as a foreign body. The liver and lungs furnish the best examples of softening of melanotic tumours, from the destruction of the tissues in which they are formed. When a portion of either of these organs is occupied by the melanotic deposit which has so accumulated as to compress or obliterate the vessels contained within it, that pass through it, or ramify in its immediate vicinity, congestion or death of the parts to which these vessels are distributed, follows as a necessary consequence. Besides this cause of effusion, (congestion,) the stimulus of the melanotic tumour is now more particularly felt, and the serous part of the blood is poured out in abundance, which, mixing with the melanotic matter, converts it into a soft pulp, or a thin dark-brown or black liquid.

It were needless to insist farther on these changes, or to combat the opinion which Laennec entertained in regard to the manner in which he imagined the last process was accomplished: that melanosis is not a tissue, but an unorganizable fluid, capable only of a certain degree of solidification, must appear obvious to every impartial pathologist who has had an opportunity of observing it in the different tissues and organs in which it is deposited, and under the various forms which it assumes.

2. *Changes induced by the melanotic deposit in the tissues and organs in which it is contained, or with which it is more or less immediately connected.*—These changes are few in number, viz. *irritation, compression*, and *ulceration.*

We have just alluded to irritation as a consequence of the presence of masses of the melanotic deposit, and the subsequent afflux of blood to the surrounding parts. It is seldom carried to the extent of inflammation and ulceration; and when either of these occurs, it is almost always confined to the tissues in immediate contact with the melanotic masses.

Compression, we have also said, may be carried to such a degree by the gradual accumulation of the melanotic deposit, that circulation ceases in the cellular tissue in which this deposit is contained. The same thing also occurs in the cellular covering of melanotic tumours, and more particularly in the skin and mucous membrane of the intestines, when, from the bulk of the tumours, these tissues become more or less stretched. Hollow organs, such as veins, the rectum, and colon, are occasionally much compressed, nearly or entirely obliterated. These effects, however, are only observed when the melanotic tumours have acquired a great bulk, and are, therefore, much

more frequently met with in the horse than in man.

Ulceration is not common as a consequence of melanosis, and in the cases in which we have observed it, it was obviously to be referred to the combined operation of the two causes mentioned above; compression, perhaps, having a greater share in its production than irritation. Thus we have only observed it in the skin and mucous membrane when greatly stretched by melanotic tumours situated beneath them. We have a very good example of ulceration of the mucous membrane of the intestines in our case of melanosis of the brain, &c.; and Breschet gives a case of ulceration of the skin of the groin produced by a large melanotic tumour situated immediately beneath it. (Loc. cit. p. 10.) Ulceration of the skin, notwithstanding its great thickness, is more frequently seen in the horse. The writer of this article has related a case in which the ulceration was accompanied with suppuration, and which may be regarded as an example of ulceration from irritation rather than from compression and subsequent obliteration of the capillaries. (Transactions of the Medico-Chirurgical Society of Edinburgh, vol. i. p. 267.) With regard to the melanotic ulcer, its form is sometimes regular, at other times very irregular; its edges thin, soft, beveled from within outwards, pale, or more or less red, or tinged with black, and a black fluid oozes from its surface. But if chronic inflammation supervenes in the tissues surrounding it, these tissues acquire a considerable degree of thickness from their being infiltrated with serosity and coagulable lymph. They thus become hard, and project around the orifice of the ulcer in the form of a broad everted border, or form on its internal surface a number of irregular projections or excrescences. When cut through, a grating sound is produced, and the cut surface presents a pale grey colour, such as is observed in scirrhus.

Ulceration from melanosis of other tissues and organs of the body has very rarely been met with. Bayle relates two cases of what he conceives to be ulceration of the lungs as a consequence of the softening of melanosis, (Recherches sur la Phthisie Pulmonaire, obs. xx. and xxi.) and which are considered in the same point of view by Laennec. (Traité d'auscult. médiate, &c. tom. ii. p. 31.) But we agree with Andral in thinking that they were cases of tubercular excavations or dilatations of the bronchi, the pulmonary tissue around them being the seat of chronic inflammation, and infiltrated with what is called black pulmonary matter.

Symptoms and Diagnosis of Melanosis. - Among the various modifications of function to which melanosis gives rise, we do not believe that the most careful examination will enable the physician to perceive in any one of them a sign of the existence of this disease in internal organs. It is only when melanosis makes its appearance externally, that he can hazard an opinion that any derangement of function is owing to its presence in one or more internal organs; that oppression and difficulty of the respiration are produced by a similar disease of the lungs, when, by means of auscultation and percussion, he finds that certain portions of the lungs are impervious to the air, without having become so by any other disease with the characters of which he is acquainted; and that ascites and œdema of the inferior extremities are in all probability the consequence of compression of the portal system of the liver, from the presence of melanotic tumour in that organ. The presence of black sputa in the first case may, under certain circumstances, afford him some assistance in establishing his diagnosis; as its quantity, and its appearance at the time that one or more of the supposed tumours in the lung have been observed to soften.

Vomiting and dejections of black matter do not afford any evidence of the existence of melanosis either in the stomach or intestines, or any other organ. The same may be said of the state of the pulse, temperature, and nutrition in general. In some cases the pulse and temperature have assumed a febrile character, and the patients become lean, pale, or sallow; changes which may be attributed to the mere mechanical presence of a great quantity of the melanotic deposit in important organs, thus operating on the one hand as a morbid stimulus, and on the other preventing the blood from undergoing various important changes. Melanosis does not appear to give rise to pain except where nerves have been impacted within, or compressed by it in some unyielding cavity. It is for this reason that the eye is generally the seat of pain in melanosis.

Prognosis. — Under whatever circumstances this disease may present itself, it ultimately proceeds to a fatal termination. It is sometimes developed with considerable rapidity, and when it occupies important organs, such as the brain or lungs, the life of the patient is seldom prolonged beyond a few weeks or months. The fatal effects of the disease are also retarded or accelerated by its extent; being greatly accelerated if it occupies the greater part or the whole of an organ, or a great number of organs at the same time, which is frequently the case, and retarded if limited to one organ or tissue. But we must again repeat that, however favourable the circumstances may be under which it first announces its existence, its tendency is to increase and ultimately to prove fatal.

Treatment.—From what we have said of this disease, it is but too obvious that any mode of treatment that can be adopted must be only palliative in its effects. To have pointed out, so minutely as we have done, the physical, anatomical, and chemical characters of melanosis, in order to show that it originates in a modification of secretion of a carbonaceous pigment analogous to the colouring matter of the blood, may, therefore, appear to the reader to be a waste of labour and of time; but we must remind him that there are a host of diseases the treatment of which is founded on no surer grounds, and respecting the history of which we know much less than we do of that of melanosis. In this respect, therefore, the scientific practitioner will at least have the advantage of being able to give a satisfactory reason for the mode of practice which he may think proper to adopt in the treatment of this very remarkable disease.

II.—Spurious Melanosis.

A. *From the introduction of carbonaceous*

matter.—Although certain forms of black discoloration of the pulmonary tissue were supposed by Laennec to originate in the inhalation of the carbonaceous product of ordinary combustion, an opinion which was previously entertained by Mr. Pearson, (Philos. Trans. 1813, part. ii,) there was no recorded fact that could be regarded as furnishing undeniable evidence of the accuracy of this opinion till lately, when a case of this kind occurred in a patient admitted into the infirmary of Edinburgh. The medical public are indebted to the late Dr. J. C. Gregory, who had charge of the patient, for the history of the case, the description of the post-mortem appearances observed in the body, and particularly in the lungs, together with the results of the chemical examination of the black matter found in this organ.* The following are the morbid appearances which were found in the lungs of this patient after death: "Both lungs presented one uniform black carbonaceous colour, pervading every part of their substance. The right lung was much disorganized, and exhibited in its upper and middle lobes several large irregular cavities communicating with one another, and traversed by numerous bands of pulmonary substance and vessels. These cavities contained a good deal of fluid, which, as well as the walls of the cavities, partook of the same black colour. A considerable portion of the pulmonary substance surrounding them was dense, hepatized, and friable. The rest of the lung was also somewhat condensed, and very œdematous. The serum, when expressed, was of the same black colour as the substance of the lung. The left lung did not appear to contain any cavities, but was condensed, and loaded with black serum. Some minute hard points could be felt in various parts of both lungs, but they did not differ at all in colour from the surrounding substance; and no distinct tubercular deposition or infiltration could be detected in those portions of the lungs which were most hepatized, even with the aid of the microscope. The texture in these parts appeared quite uniform, and the minute hard points felt in other parts rather conveyed the impression of their being merely the ends of small bronchial branches divided in making the section. The bronchial glands did not appear enlarged, but partook of the same black colour as the substance of the lungs." No other organ of the body presented any trace of this black discoloration. As a minute analysis of the black matter contained in the serum which was expressed from the substance of the lungs was made by Dr. Christison, we shall offer no apology to the reader for giving, in his own words, the results which he obtained.

"1. Concentrated nitric acid boiled on it did not alter the colour.

"2. Immersion in a strong solution of chlorine had also no effect.

"3 A strong solution of caustic potass boiled on it took up some animal matter, and filtrated very slowly The first part which passed through was opaque and black; but the last portions were of a pale yellowish-brown colour, and transparent; so that none of the black matter was dissolved. The black matter remained in the filter, and this, well washed and dried, burned like charcoal powder, without swelling up, and with scarcely any animal empyreuma, leaving a considerable pale-grey ash.

"4. A small portion of black powder, left after the action of boiling nitric acid, was well washed, dried, and introduced into a minute glass ball, with a tube attached, which was subsequently drawn out, by means of the spirit-lamp flame, to a fine bore. On the application of a low red heat to the ball, there was disengaged, at the open end of the tube, a considerable quantity of gas, which had the odour of coal gas, and on the approach of a light, took fire and burned with a dense white flame. In the tube a dark yellow fluid likewise condensed, which had very exactly the odour of impure coal-tar, naphtha, and became a soft mass on cooling, of the consistence of lard. This, when compressed between layers of filtering paper, yielded an oily stain to the paper, and left a white matter which dissolved in boiling alcohol, and separated again on cooling, in the form of minute obscure crystals."

"In the product of this experiment," says Dr. Christison, "it is scarcely possible not to recognise the ordinary products of the distillation of coal. A gas of the same quality was procured, and likewise a napthous fluid, holding in solution a crystalline principle, analogous to, if not identified with, napthaline."

The history of this case, the morbid appearances found in the lungs, and the results of the chemical analysis of the black matter in particular, do not permit of a doubt as to the origin and nature of the black discoloration of the lungs in this interesting case. The profession of the patient, which exposed him to the habitual inhalation of the coal-dust always contained in the atmosphere of a mine, and the black matter found in the lungs consisting essentially of this substance, are circumstances which demonstrate clearly the origin of the black matter, and its identity with the carbonaceous powder inhaled with the air in breathing. Besides these circumstances, the non-existence of any kind of black discoloration in any other organ of the body would furnish a strong reason for our not regarding this case as one of true melanosis. We have, indeed, never seen, nor do we know of, a case of melanosis occupying the greater part of an organ, without other organs being simultaneously affected to a greater or less extent with the same disease. Aware of this fact, we have always entertained doubts regarding the real nature of a case of black discoloration of the lungs which we had an opportunity of examining several years ago, which occurred in a middle-aged man, who was an out-patient of the Old Town Dispensary of Edinburgh. He was attended by Dr. Probart, of Bury St. Edmunds, who was then in Edinburgh, along with whom the writer of this article examined the body after death. The morbid appearances observed in the lungs were in almost every respect the same as those that have been detailed in the preceding case. The whole of both lungs was perfectly black; in many parts indurated and œdematous—in others softened and excavated. There were no tubercles, nor was

* Case of peculiar black infiltration of the whole lungs, resembling melanosis, by J. C. Gregory, M. D. &c. Edin. Med. and Surg. Journal, No. 109.

there any similar discoloration in any other part of the body.

Dr. Allen Thomson has informed us that he has likewise seen a similar case of black discoloration of both lungs. No analysis of the black matter in either of these cases was made; and besides, not having been able to ascertain the profession of either of the patients, our opinion with regard to the origin and nature of the black discoloration of the lungs in both cases, must be founded entirely on the anatomical facts to which we have alluded, viz. the universal black discoloration of both lungs, and the non-existence of any similar discoloration of any other organ or tissue of the body.

[Since then, many other cases have been observed. The affection has received the name of black lung of coal miners, and by Dr. Stratton (*Edinb. Med. & Surg. Jour.*, April 1838, p. 490) it has been termed *Anthracosis.*]

It is surprising that no case of universal black discoloration of the lungs produced by the inhalation of carbonaceous matter is to be found on record previous to that of Dr. Gregory, when we reflect that so many individuals are daily exposed in this country to the cause by which it is produced. We can hardly attribute this silence, on the existence of such a conspicuous morbid state, to the paucity of post-mortem examinations. Is it not more probable that the accumulation of the carbonaceous matter in the lungs is determined by a morbid state of these organs?—that, although carried into the lungs with the air, it is removed by expectoration or absorption, and its accumulation in these viscera thereby prevented? We are, indeed, much disposed to believe that these circumstances must tend to favour or prevent the occurrence of this diseased state of the lungs. In the cases referred to, we have not been able to ascertain that there existed any particular morbid state of the lungs which could have prevented or favoured the accumulation of the inspired carbonaceous matter. We, however, consider it a subject worthy the attention of the medical practitioner who has the opportunity of studying the diseases of persons employed in coal-mines, whether the black discoloration of the lungs is observed to occur in those only who have suffered from pulmonary complaints; although it may be often difficult to discriminate between cause and effect, between the original disease and the changes which must take place in the structure and functions of the lungs from the presence of the inspired carbonaceous substance.

Symptoms.—The symptoms presented by Dr. Gregory's patient as well as our own, were referrible to the presence of the inspired carbonaceous matter, acting, 1st, mechanically, and giving rise to atrophy of the pulmonary tissue, compression and obliteration of the air-cells, bronchi, and blood-vessels; and, 2d, as a foreign body, producing a greater or less degree of irritation. To these modifications of the pulmonary organs are to be ascribed the local symptoms, such as the dyspnœa, cough, the mucous and cavernous *râles*, and the increased secretion and expectoration of mucus. The presence of black matter in the expectorated fluids was no doubt to be attributed to the existence of a direct communication between some of the bronchi and the excavations formed in the substance of the lung. Although there were also softening and excavation of the lungs in the case which we examined, it does not appear from the account which we have received of the history of the case, that the sputa were discoloured by the admixture of black matter; and as it is stated that the mucous *râles* heard in this case were remarkably strong, but not *cavernous*, it may be presumed that the absence of the black matter was owing to there being no communication between the bronchi and the softened or excavated portions of the lung, or that the solidification of this organ was so great from the presence of the carbonaceous matter, that the former did not admit of being sufficiently compressed to expel any of this substance with the mucous secretion of the bronchi.

The general symptoms produced by the accumulation of the carbonaceous matter in the lungs, were chiefly the general cachectic condition of the body and anasarca, both of them depending on the state of the pulmonary circulation. The great diminution in the quantity of the blood admitted into the lungs, which must necessarily have followed the presence of such a quantity of foreign matter in this organ, as well as the imperfect change which must have been effected in that which was allowed to pass through the pulmonary vessels, will sufficiently explain the cachectic state of the patient. The anasarca must also be attributed to the same cause, viz. the presence of the accumulated carbonaceous matter, and its mechanical effects on the pulmonary veins, thereby giving rise to general venous congestion and effusion of serosity into the cellular tissue.

Diagnosis.—Being in possession of such a limited number of facts in regard to this singular, if not rare, affection of the lungs, we should not feel justified were we to assign to it characters by means of which it may be distinguished from certain organic affections to which the same organs are subject. We, indeed, know of no modification of function, local or general, by means of which this form of spurious melanosis is to be distinguished from true melanosis of the lungs. We may, however, suggest that, as the former pervades the whole of both lungs, dyspnœa may be greater than in the latter, which always leaves a portion, and often a considerable extent of lung in the healthy state;—that respiration will be found to be natural, or nearly so, in several portions of the lung affected with true melanosis; whilst in the spurious form of the disease, depending on the universal deposition and accumulation of inhaled carbonaceous matter, the respiratory sound, or at least the respiratory *murmur*, that which takes place in the air-cells, will either be greatly obscured or inaudible, and will be replaced by *bronchial* respiration, the *ronflement* and *sonorous râles* which accompany the solidification or condensation of the pulmonary tissue. We need hardly mention that the presence of black matter in the sputa cannot be regarded as a *pathognomonic* sign, unless its real nature has been determined by chemical analysis.

The only other disease with which this spurious form of melanosis is likely to be confounded, is chronic catarrh. We are, however, disposed to believe that the presence of anasarca, as well as

the dull sound of the chest on percussion, will be sufficient to enable us to distinguish the former disease from the latter, in which the sound of the chest is not materially affected, and which is not accompanied with anasarca, unless it be complicated with disease of the heart. The emaciation, diarrhœa, and hectic, which accompany phthisis, will prevent the physician from confounding this disease with spurious melanosis of the lungs, even when the latter has given rise to softening and excavation of the pulmonary tissue.

Treatment.—Imperfect as the description may be which we have given of the changes produced in the structure and functions of the lungs, originating in the inhalation of carbonaceous matter, and in its accumulation in these organs, it is sufficiently obvious that neither the local effects to which the presence of this foreign substance gives rise, nor the general disturbance of nutrition and circulation which follows as a consequence of the former, can be remedied so long as the offending cause remains. How far the removal of this can be accomplished by means of remedies which act chiefly on the absorbent system, is a point which remains to be determined by future observation and experiment.

If the disease has proceeded to such an extent as to produce general atrophy of the pulmonary tissue, softening and excavations in various portions of the lungs, its fatal termination must be inevitable. We cannot, therefore, too strongly impress on the mind of the physician who has the opportunity of doing so, the importance of ascertaining the early signs of this affection, as well as the influence which other diseases may have in favouring its production, as a knowledge of both circumstances will suggest the means to be employed either for its cure or the prevention of its occurrence.

B. *From the action of chemical agents.*—The next kind of melanotic formation which we have to describe, is that which is produced by the action of certain chemical agents on the blood.

Our attention was for the first time drawn to this subject nearly three years ago, while making a series of experiments on the chemical dissolution or digestion of the walls of the stomach after death. With regard to the subject of these experiments, it is necessary to observe, that the partial or complete dissolution of one or all of the coats of the stomach was found to take place after death, and to be the invariable consequence of the chemical action of an acid fluid contained in the cavity of that organ. A peculiar change in the colour of the blood contained in the veins of the stomach, was also observed to accompany the chemical dissolution of the walls of that organ, and which, though less frequent in its occurrence than the latter, was not the less obviously the effect of the same chemical cause; for, firstly, there was no discoloration of the blood when there was no softening or chemical dissolution of the coats of the stomach: secondly, the discoloration of the blood was observed only in the vessels distributed, or near, to those parts of the stomach which were softened: and thirdly, that both changes were, *cæteris paribus*, nearly in the same ratio as to degree and extent. Although these circumstances might have been regarded by us as affording sufficient evidence that the discoloration of the blood was produced by the direct operation of the same chemical agent by means of which the dissolution of the walls of the stomach was effected, we made several experiments on this interesting and important subject, the results of which leave no doubt as to the accuracy of our former conclusion,—viz. that the discoloration of the blood which accompanies the chemical dissolution of the walls of the stomach, is a direct effect of an acid fluid contained in the cavity of that organ, or, as we shall afterwards call it, the gastric acid.* If we kill an animal, a rabbit, for example, or open it while alive, and during the process of digestion, the fundus of the stomach is always found to contain a quantity of this acid, mixed with the food in this the depending part of the organ. When the stomach is laid open, a sour smell is immediately perceived to arise from its contents; and if a portion of litmus paper is placed in contact with the latter, it acquires, almost instantaneously, a beautiful red colour. If arterial or venous blood is allowed to flow into the stomach from some of the neighbouring vessels, so soon as it comes in contact with the digested portion of the food, or that in which the gastric acid is most abundant, its natural colour is almost immediately changed to deep brown or black. The rapidity with which this change takes place in the colour of the blood, as well as the degree and extent to which it proceeds, varies with the strength of the gastric acid and the quantity of the blood on which it is made to act. When the digested acid food, or the gastric acid alone, is removed from the stomach in which it was found, and is put into another stomach, or other organ, the vessels of which are conspicuous and filled with blood, this fluid very soon undergoes the same change of colour which we have said takes place when it is poured upon the digested food, and, consequently, when in immediate contact with the chemical agent by which this change is effected.

These facts show clearly that healthy blood contained in the cavity of the stomach, or in the vessels of that organ, in a dead animal, is changed to a dark brown or black fluid. But the influence of the gastric acid in producing this change in the blood, is not limited by the conditions to which we have just alluded. Not only is the blood that has been poured into the cavity of the stomach or is contained in the vessels of the mucous and submucous tissues, changed from red to brown or black, but likewise that of the sub-peritoneal vessels of the same organ is similarly altered. We have also seen the same black discoloration of the blood in the sub-peritoneal vessels of a neighbouring organ, such as the liver, spleen, intestine, or diaphragm, in contact with that portion of the stomach which contained half-digested food or gastric acid. Hence we can readily conceive that if blood is effused into the cavity of the peritoneum, and in the vicinity of the stomach, it will undergo the same change of colour as that which we have said takes place in this fluid when contained in its proper vessels beneath this membrane. We have

*We employ the term *gastric acid*, because it indicates the seat, and, particularly, the *property* of the chemical agent by means of which the dissolution of the walls of the stomach, and the black discoloration of the blood in that organ, are produced.

produced effusion of blood into the cavity of the peritoneum around the stomach, in several animals, and have thus been able to witness its conversion from red to brown or the deepest black.

The discoloration of the blood in these situations external to the stomach, and depending on the influence of the gastric acid, is an interesting fact, with the nature and origin of which we were entirely ignorant until we observed the effects of this chemical agent on the blood contained in the vessels of the stomach. It is perfectly obvious, from what we have said, that we have, in both cases, the same efficient cause. We have taken a portion of stomach containing gastric juice, placed it on a coagulum of blood or kept it in close contact with a portion of intestine on which there was a greater or less number of vessels filled with red blood. In both cases the blood assumed a brown or black colour, no doubt from the acid having been carried from the interior of the stomach by imbibition.

There is still another mode in which the black discoloration of the blood may be produced by the gastric acid, viz., when this fluid is effused into the cavity of the peritoneum through an opening which it has made, generally in the fundus of the stomach. It occupies the most depending parts, dissolves the tissues with which it comes in contact, perforates the diaphragm, and passes into the cavity of the thorax. Along with these remarkable effects of the gastric acid, the black discoloration of the blood is no less conspicuous in all the parts on which its chemical influence has been exerted.

Such is a very general sketch of the several modes in which the black discoloration of the blood is produced, when this fluid is exposed to the mediate or immediate influence of the gastric acid. We have already stated that this condition of the blood was not produced till after the death of the animals submitted to our experiments; that these animals were in the enjoyment of the most perfect state of health when killed; and that the gastric juice possessed that property—acidity—by which it is always distinguished during the act of digestion. These facts are the more important when we consider that they establish the formation of a series of changes in the blood after death, which are entirely independent of any morbid condition, local or general, of the animal in which these changes are observed. It is necessary, however, to state that there are two conditions in which the blood may be placed during life, which render it susceptible of being acted upon by the gastric acid: first, when it has ceased, during an uncertain period of time, to circulate; secondly, when it is effused into the cavity of an organ. In both circumstances it is deprived of those properties by means of which it is enabled to resist, to a certain degree, the destructive influence of external agents; and, therefore, undergoes the same changes when submitted to the action of the gastric acid, as it does after death.

Locality and Order of frequency of the Black Discoloration of the Blood, from the operation of an Acid Chemical Agent.—As the black discoloration of the blood of which we are now treating is produced by the operation of an acid chemical agent, it is consequently met with only in those organs in which this agent exists as a healthy or morbid product, or to which its influence extends in the manner which we have already stated. Hence, as the stomach is the only organ of the body in which an acid fluid is formed, and is at the same time a healthy product, the black discoloration of the blood is nowhere so frequently observed, so conspicuous, and so extensive as in this organ. The same discoloration of the blood, as to locality and order of frequency, occurs in the intestines, from the anormal formation of a fluid and gaseous acid product. It is owing to the proximity of the peritoneum to these normal and anormal acid products, that blood situated beneath this membrane on its free surface or in its cavity undergoes so often the change of colour in question; and it is to the same circumstance of situation that portions of the liver and spleen are so frequently found to present the same dark colour. The dark discoloration of the blood in the intestines and in the other situations just named, depends, perhaps, more frequently on the presence of sulphuretted hydrogen gas than an acid fluid in the former, owing, no doubt, to this gas possessing the properties of an acid.

Natural and accidental tissues, remote from the stomach and intestines, are also observed to present various kinds of discoloration; but we allude to those which chiefly depend on the presence of various shades of blue, brown, and black. The blue discoloration, which is sometimes very deep, approaching to black, is most frequently observed to occupy the walls of chronic abscesses in various parts of the body. It is not the consequence of putrefaction, but is produced by the presence of a chemical agent, the nature of which we have not been able to ascertain. The brown and black discolorations are observed to accompany the death of parts, preceded or followed by a local accumulation of blood. It is probable that they sometimes originate in the formation of an acid product, which afterwards acts upon the blood; although they are certainly owing, in general, to changes which take place in the blood itself of the dead part, for which reason we shall refer them to the fourth division of our subject, which contains the description of the black discoloration of the blood from stagnation of this fluid, and the subsequent changes which it undergoes.

Form, Situation, and Extent of the Black Discoloration of the Blood.

1. *In the vessels of the Stomach.*—The blood which undergoes this change of colour derives the peculiarity of the forms which it assumes from its being contained in its proper vessels. The three following forms are the most conspicuous: the punctiform, uniform, and ramiform. All these forms of black discoloration of the blood are met with either separately or combined, and may occupy a portion or the whole surface of the stomach. They are most frequently observed in the fundus of the stomach, for the reasons already assigned; but they may exist in other parts of this organ, as the pyloric portion, small and great curvatures, to which external causes, such as tumours, distension of the colon, enlargement of the spleen, &c., have given a more depending position than that of the fundus, consequently favouring the accumulation of the gastric acid in

these parts after death. The situation of these forms of black discoloration of the blood is also modified by the quantity and quality of the contents of the stomach. Thus, if the stomach is nearly empty, the discoloration of the blood is confined to the surface of the rugæ formed by the mucous membrane; and if it is distended by a quantity of gas, the discoloration is limited to the depending part of the organ, and terminates in a defined margin, the course and extent of which are determined by the superposed gas, which has prevented the gastric acid from acting beyond the limits within which it was thus confined. And, lastly, if the stomach is filled with gastric acid, as sometimes happens in stricture of the pylorus, the whole surface of the mucous membrane may present a uniform dark brown or black tint.

With regard to these three forms of the black discoloration of the blood in the vessels of the stomach, it is only further necessary to observe, that although the punctiform and uniform are more frequently produced than the ramiform, on account of the small veins being more often filled with blood than the large ones, the ramiform is most frequently seen; a circumstance which is owing to the mucous membrane and the minute veins within it and beneath it being sooner dissolved by the gastric acid than the large veins. In the punctiform discoloration of the blood, the mucous membrane presents an appearance as if it were dusted over with a quantity of fine charcoal powder; and when the discoloration is uniform, it appears as if painted with bistre or china ink, in the form of patches or streaks of various forms and dimensions. The ramiform discoloration is generally the most conspicuous and striking of the three, because of the black blood being contained in veins of considerable size. They appear as if they had been injected with chocolate or a mixture of soot and water. The dark blood presents a *curdled* appearance. It does not fill the veins, but is separated and agglomerated into small masses, which become gradually less towards the minute branches, and there appear in the form of black points, having still a ramiform distribution, but are no longer contained within the walls of the veins, the former having been dissolved by the gastric acid. This is the form of the black discoloration of the blood which we have said has been described as melanosis of this fluid, — an opinion which we hope the preceding details have shown to be erroneous.

2. *Black discoloration of the blood in the vessels of the intestines.*—From what we have already said of this change of the blood in the vessels of the stomach, we have only to add that it is less frequently observed in those of the intestines, is seldom so conspicuous, and that it assumes in general the punctiform arrangement. This character of the black discoloration in the intestines is owing to the change of colour taking place in the blood contained in the vessels of the villosites or isolated follicles. The black punctiform discoloration is sometimes observed to occupy the mucous membrane of the greater part of the intestines, both large and small; but we believe it is most frequently seen in the inferior portion of the ileon and in the duodenum.

A similar discoloration of the blood in the vessels of the villosites and isolated follicles is met with in various portions of the intestines in particular, and which is not produced by the action of an acid on the blood. It is the consequence of stagnation, and is not to be distinguished from the former otherwise than by ascertaining the nature of the contents of the intestines in which it is observed.

3. *Black discoloration of the blood effused into the cavity of the stomach and intestines.*—The fact of the black discoloration of the blood effused into the cavity of the stomach and intestines being produced by the chemical action of an acid fluid or gas contained in these situations, does not appear to us to have been even suspected till after the results of our experiments on this subject were made known. If we consult the works that have been published on melæna, (a disease characterized by the presence of black matter in the fluids ejected from the stomach and bowels,) we shall find that the opinions therein expressed, in regard to the black discoloration of the blood in this disease, were founded on mere conjecture.

By some pathologists the black discoloration of the blood was believed to take place in the venous system; by others, that it was not effected till after the blood was effused into the cavity of the stomach or intestines, and that the red colour of the blood was then converted into black by the fluid or gaseous contents of these organs. The latter opinion was, however, entirely conjectural, such conversion of the blood never having been *seen* to take place. Notwithstanding the importance of the subject, it was never submitted to the test of experiment. The matter of black vomit and dejections was *believed* to be blood *altered* in the stomach and intestines, but whether by a chemical or vital agent was quite undetermined. From the results which we have given of our experiments on this particular point at the commencement of this article, it must appear obvious that blood effused into the cavity of the stomach is almost immediately converted into a deep brown or black colour, and, moreover, that this change of colour is owing to the presence of a chemical agent; that this agent is an acid, similar in all its properties to that by means of which the dissolution of the food during digestion is accomplished. We have also stated that, if this acid fluid is not present, as is frequently the case, no such change of the blood introduced into the cavity of the stomach takes place — it preserves its natural colour: and again, that if the quantity of the blood be so considerable as not to be acted upon uniformly by the acid, only a portion of it is black, whilst the rest is of its natural colour. These circumstances relative to the presence or absence of the gastric acid, and the quantity of blood submitted to its action, appear to us to furnish the most satisfactory explanation of the essential phenomena of melæna. They further show that there is, properly speaking, no difference between this disease and hæmatemesis. Both of them originate in the effusion of blood, no matter how produced, whether by exhalation or a solution of continuity. In the latter the blood preserves its natural colour; in the former it is black, because of the reasons just stated—the presence of an acid in the one case, and its absence in the other. On

these circumstances alone can the pathologist be justified in making a distinction between hæmatemesis and melæna.

As this part of our subject is, as we have seen, intimately connected with the latter disease, we shall only further add, that the black discoloration of the blood in the stomach is found to accompany cancer of this organ much more frequently than any other disease. Black vomit almost always accompanies the last stage of this disease,—that is to say, the stage of softening, because of the hemorrhage which then takes place. Next in the order of frequency is follicular ulceration of this organ. In the intestines follicular ulceration is by far the most frequent change which is observed to accompany black dejections. In both organs the ulceration of the follicles is sometimes so extremely limited that it is not perceived until after the mucous membrane has been well washed and exposed to a strong light, when it is seen to occupy the central portion or orifices of the follicles in the form of a red point, with an irregular circumference, probably the ulcerated border of the orifices of these follicles. Next in the order of succession are the numerous diseases of the heart and its orifices, and several of those of the liver and vena portæ, which obstruct mechanically the return of the venous blood, and thus determine its effusion from the digestive mucous membrane. And, lastly, we have met with the same discoloration of the blood in individuals the most feeble and emaciated, in whom this fluid appeared to have almost entirely lost that plastic property on which its coagulation depends, and by means of which its effusion is prevented when accumulated in the capillary system.

The black discoloration of the blood in the vessels of the stomach, produced by the gastric acid after death, is a subject of the greatest importance to the toxicologist, particularly when considered in connection with the effects which result from the operations of all poisons possessing acid properties on the blood. Although we have directed our attention to this subject, and have been able to ascertain that several of the changes produced in the blood under these opposite circumstances are so characteristic as to afford us the means of determining their nature and origin, we are prevented from making any further allusion to them, because of the minute descriptive details, into which we should be obliged to enter, were we to attempt to put the reader in possession of the means whereby he might distinguish post-mortem from pathological black discoloration of the blood in the digestive organs. We must therefore refer him for further information on this subject to the article PSEUDOMORBID APPEARANCES.

4. *Black discoloration of the blood on the surface or in the cavity of the peritoneum.*—As we have already alluded to the manner in which the black discoloration of the blood takes place in these situations, we shall only notice a few circumstances of importance with regard to its seat, and the lesions which it most frequently accompanies.

We have already said that it is met with in the vessels which ramify under the peritoneum; but it is more frequently seen in those which exist in the false membranes of chronic peritonitis. When the blood is effused into the sub-peritoneal tissue, on the surface of the peritoneum, into its cavity, or into false membranes, the black discoloration which it undergoes is remarkably conspicuous, and frequently occupies a great extent of surface. It is only when the discoloured blood is contained within its vessels that it presents, in the situations just named, a ramiform distribution. There is, however, a peculiar modification of this form which requires to be noticed. It occurs in chronic tubercular peritonitis. The tubercles scattered over a greater or less extent of the peritoneum, are surrounded by a dark ring, or a multitude of minute vessels filled with black blood, having a stellated arrangement. If the tubercles are very minute, they are obscured by these appearances, and the peritoneum seems as if spotted with a deep brown or black pigment, which has been described as melanosis of the peritoneum.

The black discoloration of the blood when effused on the surface of the peritoneum or into false membranes, has still more frequently been taken for melanosis, and described as such. It then assumes the appearance of black patches, striæ, or layers of various extent, occupying either the visceral or abdominal portions of the peritoneum, or both at the same time. If the effused blood has collected in the cavity of the peritoneum, it undergoes the same change of colour which we have seen takes place in the blood effused into the cavity of the stomach and intestines. The external portion of the blood, or that which is in contact with the peritoneal surface of the intestines, is always deepest in colour, being sometimes as black as pitch; whilst that which is more remotely situated is either of its natural colour, or but slightly darkened. From these circumstances, and from what we have already said on the effects of the acid fluid and gaseous contents of the stomach and intestines, there can be no doubt that the black discoloration of the blood contained in the cavity of the peritoneum is owing to the chemical operation of these products. In confirmation of the accuracy of our opinion on this point, we may mention that we have had several opportunities of seeing the blood effused into the cavity of the peritoneum, undergo the change in question, in individuals who died from hemorrhage in consequence of wounds of the abdominal viscera. Although the description which we have given of the forms, situation, and extent of the dark discoloration of the blood in the digestive organs, and in those situated in their immediate vicinity, will in general enable the practical pathologist to recognise them in his post-mortem examinations, we would recommend him in all doubtful cases to *test* the contents of the former organs. A sour smell may not be always sufficiently strong to be perceived; and besides, his having determined (by means of litmus paper, for example, some of which he should always have in his case of instruments,) chemically, the presence of an acid, every doubt will be removed as to the nature of the black discoloration of the blood in the parts which we have named.

C. *From the stagnation of the Blood.*—Black discoloration of the blood has been long known to follow as a consequence of retarded or interrupted

circulation. This change in the colour of the blood is never so conspicuous as when it takes place in the extreme venous circulation, or in the capillaries; and it is only when it occurs in the latter situations that it has been described as a form of melanosis. We shall, therefore, confine our remarks to the black discoloration of the blood, which follows in consequence of the stagnation of this fluid in the capillary circulation. It is worthy of remark, that the black discoloration of the blood originating in this cause is much more frequently observed in some organs than in others, and is never so conspicuous or extensive in young as it is in old persons. The circulation of the capillaries being influenced by that of the heart and great blood-vessels, it is also frequently observed to accompany diseases of the latter organs, which impede the circulation of the blood in general, and give rise to a state of venous congestion. Among the local causes of its production, acute and chronic inflammation are the most frequent. This change in the colour of the blood has not, however, been regarded as a matter of much importance in acute inflammation; whilst in chronic inflammation on the contrary, it has received much attention, as its presence has been considered as one of the least equivocal characters of this disease. To these causes of the stagnation of the blood and its subsequent black discoloration, we may also add debility, which gives rise to similar states of the blood in depending parts of the body, but more particularly the inferior extremities.

Under the influence of these causes, the blood accumulates in the capillaries, and ultimately ceases to circulate. After a certain length of time it coagulates, and the serum is forced out along with the salts which are absorbed. That which remains is an almost black substance, of the consistence of firm fibrine, and is probably composed in great part of the animal principle and hematosine. The black colour thus produced appears to us to receive a satisfactory explanation from the circumstance that it follows the stagnation and coagulation of the blood, and consequently the separation and removal of the serous and saline ingredients of this fluid, to the latter of which, as has been clearly demonstrated by Dr. Stevens, its red colour is to be attributed.

The degree and extent of the black discoloration of the blood from stagnation of this fluid will no doubt vary in different individuals, in different organs, and under the influence of different diseases. Thus it is, generally speaking, most frequently observed in persons whose circulation is low; frequently, as we have already said, in the old and infirm, and seldom in the young and healthy; and in those diseases which mechanically or otherwise impede or interrupt the capillary circulation. As we have already extended this article far beyond the limits which we had originally prescribed to it, we shall confine the few remarks which we have yet to make on this part of our subject, to the presence of the black discoloration of the blood in particular organs and diseases, and some of its forms.

There are, strictly speaking, only two organs, the respiratory and digestive, in which this change of the blood bears any resemblance to true melanosis.

1. *Black discoloration of the blood from stagnation in the lungs.*—This change of the blood in the lungs occurs most frequently at an advanced period of life; in phthisis pulmonalis; in chronic catarrh; in emphysema; in dilatation of the bronchi; in induration of the pulmonary tissue; in disease of the heart; in one word, in whatever diseases impede the pulmonary circulation, and render the function of respiration imperfect. The black discoloration of the blood in the lungs is general, if the diseased condition in which it originates has exercised its influence on the venous circulation of these organs in general, as in disease of the heart; and it is confined to a limited extent, although it may occupy a greater or less number of separate points, when produced by local causes, such as tubercles. In the former case, the black discoloration of the blood is seen most conspicuously in the vessels of the inter and intra-lobular tissue. In the former tissue it has a ramiform disposition, in the latter it is capilliform and punctiform; appearances which are best seen on the serous surface of the lung. In the latter case, the vessels containing the black matter occupy the circumference of the tubercles, and have a stellated arrangement. In emphysema, dilatation of the bronchi, induration of the pulmonary tissue around tubercular excavations, the black discoloration is often very extensive, on account of the great obstacle which these morbid states oppose to the return of the venous blood, and the length of time which they have continued to operate.

Chronic inflammation of the pulmonary tissue gives rise to the same form of black discoloration of the blood which we have just said accompanies induration, because of induration being, in general, the consequence of this state of inflammation. Chronic inflammation of the lungs may, however, produce the same change in the blood without being accompanied by induration.

The mucous membrane of the bronchi seldom presents the grey or slate colour so common in the mucous membrane of the digestive organs,—a circumstance that would seem to indicate that these membranes are not exposed to the influence of the same agents to which we ascribe the black discoloration of the blood in question, in the respective organs to which they belong. Be this as it may, the black discoloration of the blood in the mucous membrane of the bronchi is seldom considerable, and is rarely observed, unless in old persons whose lungs are at the same time extensively affected with it. It is also best seen in the bronchi which communicate with tubercular excavations, and in the vicinity of ulcers of the mucous membrane itself.

Black discoloration of the bronchial glands, with regard both to frequency and degree, has appeared to us to occur under the influence of the same causes which give rise to the black discoloration of the blood in the lungs. It is most frequently seen and most marked in the bronchial glands of old persons, and it may occur even in children with tubercular phthisis.

2. *Black discoloration of the blood from stagnation in the digestive organs.*—This change in the colour of the blood is almost exclusively confined to the mucous membrane of the stomach

and intestines, and follows as a consequence either of chronic inflammation of that membrane, or of diseases of the heart or liver which impede the return of the venous blood. It is limited to a portion of the mucous membrane when preceded by irritation, and if it accompanies chronic ulceration of this membrane or of its follicles, it is often very conspicuous. When produced by an obstacle to the return of the venous blood, particularly if the obstacle is situated in the vena portæ, it may occupy the mucous membrane of the stomach and of the greater part of the intestines. In both cases the mucous membrane presents a grey, greyish-brown, or slate colour, which is either punctiform or uniform; and which, when examined with a lens, is seen to depend on the presence of a similar coloured fluid contained in the capillaries. The mucous membrane is at the same time thicker than natural, and the follicles and villositics are in some cases hypertrophied.

The appearances produced by the black discoloration of the blood from stagnation in the stomach and intestines, are very similar to those which are the effect of the chemical action of acid fluid and gaseous products contained in these organs. In order, therefore, to distinguish the former kind of discoloration from the latter, it is often nesessary to ascertain that no acid chemical agent is present. From the result of our own observations we are led to believe that the grey slate colour of the mucous membrane is too exclusively received as a physical character of chronic inflammation. That it does take place as a consequence of this pathological state there can be no doubt, inasmuch as we see it produced, for example, in the mucous membrane of the vagina and in the skin from this cause; but, as we have already observed, it is of comparatively rare occurrence in the bronchial mucous membrane, which is perhaps as often the seat of chronic inflammation as the mucous membrane of the digestive organs. It is on account of this circumstance, as well as from actual observation and experiment, that we are led to believe that this character of chronic inflammation of the digestive organs has frequently been mistaken for the discoloration of the blood produced by chemical action of the acid contents of these organs.

R. Carswell.

MENINGITIS. See Brain, Inflammation of.

MENORRHAGIA. This term (derived from *μήνη, mensis*, and *ῥήγνυμι, rumpo*) implies morbidly profuse menstruation. Some authors have attempted a distinction between those cases where the menstrual discharge is simply over-abundant, and those where, along with the peculiar menstrual secretion, pure blood is expelled. Dr. Mackintosh of Edinburgh, and Mr. Burns of Glasgow, have restricted the name of menorrhagia to the latter description of cases, calling the former only immoderate flow of the menses. Others, again, have chosen to class those instances where a mixture of pure blood is passed, under the head of uterine hemorrhage. The great object ought to be, not to mislead by too nice and critical refinement in nomenclature. The term uterine hemorrhage is so constantly limited in practice to cases unconnected with menstruation, and occasioned by organic disease, accidental injury, or the consequences of pregnancy or parturition, that it is much more convenient to include under the title at the head of this article all those instances of the discharge of real blood from the uterus which occur in connection with the menstrual functions. The cases, indeed, are very rare in which any strikingly profuse menstruation exists, without more or less of real blood escaping at the same time. Dr. Dewees states that, in a very extensive practice of many years' duration, he has scarcely ever known a case of genuine menorrhagia without the admixture of pure blood. (System of Midwifery, p. 147.)

Menorrhagia is a disease occasionally of great obstinacy, sometimes of alarming severity; and as much of the success of the treatment depends upon a proper discrimination of the different conditions which give rise to it, it becomes necessary to point out somewhat at length in what this difference consists. At the same time it must be acknowledged that it will be impossible to go minutely into every variety of case which may occur in practice.

Menorrhagia not only includes the immoderate quantity of discharge at each monthly period, the time remaining regular; but it is also understood to comprehend the too great frequency of the recurrence of menstruation, even when the quantity lost is not unusually abundant: still the definition of "morbidly profuse menstruation" ought to be remembered, because to constitute the disease the quantity lost must be relative. Many women remain in perfect health who are accustomed to a very considerable discharge regularly, thus menstruating every two or three weeks habitually; and yet, as long as the health continues unimpaired, or nothing more than has always been usual takes place, it would scarcely ever happen that medical advice would be applied for to abate the symptoms. In healthy menstruation the discharge takes place every twenty-eight days, lasts from three to four days, and the quantity lost upon an average is about five or six ounces. But this is merely a general rule: the exceptions are numerous; and it is only when it becomes an exception to the individual's ordinary habits, that disease should be considered to exist. The effect of climate in these cases is very remarkable; and what would be considered a very scanty menstruation in the warmer climates of the east, would be deemed menorrhagia in Lapland. A curious blunder was committed in this respect by Dr. Freind, who stated that the quantity of menstrual discharge in this country averaged about twenty ounces—a menorrhagic excess by no means common; the mistake arising from his having quoted Hippocrates without reflecting that the *δύο κότυλαι Ἀττικαι* applied only to the females of Greece.

Menorrhagia may occur in very opposite states of the system, and has therefore been divided into active and passive; the former arising from too great activity in the vessels of the uterus, the latter from a want of tone in their secreting orifices. Either of these states may exist in a plethoric habit of body, or in one of great debility; but in general the local condition is of the same character with the constitutional in the same individual. After a long continuance of the disorder, the

strongest and most plethoric frames are brought down to the state of weakness, and the active menorrhagia may thus become passive. In active menorrhagia, for a short time, sometimes for two or three days before the expected period, there is a sensation of unusual fulness about the pelvis, with throbbing referred to the situation of the uterus itself, along with sense of heat and weight; the external parts of generation are often slightly swollen, and the mammæ become hot, tumid, and painful. The circulation is quickened, the mouth hot, the tongue dry with thirst, and there is a general feeling of oppression, with headach and giddiness. After these symptoms have lasted for a certain time, the function of menstruation begins; but the discharge comes on with violence, in gushes, and usually accompanied with pure blood, as proved by the presence of coagula. The progress is then variable; sometimes after the first few hours the patient feels relieved, lighter, and cooler, and the rest of the period passes over more quietly and naturally; but in more aggravated cases the flow still proceeds in equal or increased quantity, and lasts for several days, occasionally subdued, but again breaking forth on the slightest exertion, till at the end of the period the patient is left weak and languid, with a feeble pulse and a pale countenance. By the time of the recurrence of the monthly period the individual is perhaps restored to the previous state of health; but the same train of circumstances is again renewed with perhaps increased severity; and the complaint rarely lasts long without the number of days intervening between the periods being rapidly diminished, till at last scarcely one period is over before the next approaches. The condition then quickly becomes one of passive menorrhagia, both local and general, the symptoms of which are more formidable, and the treatment more difficult.

The patient in passive menorrhagia is habitually languid and with feeble powers, or may have become so from previous long-continued loss of blood in the more active form of the disease. She is subject, perhaps, to palpitations of the heart, and violent headachs with throbbing and beating in the temples, singing in the ears, and giddiness—all arising, not from plethora or absolute determination of blood to the head, but from exhaustion and relative determination. This is a very important distinction, and one which has been too frequently and often fatally overlooked. For a further investigation of this interesting subject the reader is referred to the experiments of Dr. Kellie of Leith, and the practical observations of Dr. Marshall Hall; and also to the article BLOODLETTING in the present work. For the difference in the pathology of active and passive menorrhagia, we may also refer to the able article HEMORRHAGE, in which is comprehended much that will apply to the morbidly profuse menstruation, the circumstances being but very slightly modified by the periodical nature of the discharge, and the fact of its being merely an excess of a natural one.

In passive menorrhagia there are rarely any precursory symptoms; if the periods are still regular as to time, they are irregular and unnatural as to duration and the quantity lost. In general the return is also much too frequent, so that at last one period is followed nearly immediately by another, or there will be one continued discharge, varying from time to time in profuseness, from a mere oozing of a thin, half serous discharge, to the full gushes of coagulating blood. When apparently the discharge is safely over, the least excitement of body or mind, the slightest exertion or disturbance, will reproduce it, and the difficulties are again as great as ever. The usual effects of morbid loss of blood gradually or rapidly present themselves. When the complaint has been of long standing, but not very suddenly violent, the complexion becomes sallow and cadaverous; the countenance either pinched and emaciated, or bloated and anasarcous; the pulse rapid and feeble; the legs and feet, and often the whole of the cellular membrane distended with fluid; the respiration short and difficult; and, in fact, all the symptoms of confirmed and extreme cachexia are observed. But the most dangerous character of the complaint is manifested in the sometimes suddenly profuse menorrhagic discharge, the absolute danger being much influenced by the previous resisting power of the individual. In these instances alarming syncope has occasionally been brought on, and the most active measures become imperatively necessary, to rescue the patient, and prevent a fatal termination. Instances of death would no doubt be much more frequent, did we not possess very efficient means in general to arrest the discharge. Besides the exhaustion from the menorrhagia itself, it is nearly always the case that patients are afflicted in the intervals with profuse leucorrhœa; and if they are exposed to become pregnant, abortion will be very apt to follow. We have also frequently remarked that those who have suffered much from menorrhagia, are peculiarly liable to uterine hemorrhage after abortion or parturition at the full time.

There is one species of menorrhagia which is not uncommonly met with in practice, and yet has not, we believe, been noticed in books,—where, instead of the periods being regular to the month, or much more frequent than ordinary, the interval is protracted considerably, even to six, seven, or eight weeks. In these instances, whenever the menstruation is regular to the usual time, the discharge is not excessive; but upon any disturbance to the general health, there is more or less of delay, and the discharge is then morbidly profuse. This is common both with married and unmarried women; but when it takes place with the former, it is very frequently mistaken for abortion, being often accompanied by pain and the expulsion of solid masses of coagulated blood with flakes of albumen, not very unlike an early ovum. These women are said in common language to become *obstructed*, but it is under very different circumstances from amenorrhœa, as the protracted period is always followed by profuse hemorrhage. The patients complain for several days, even for two or three weeks, previous to the appearance of the discharge, of the symptoms mentioned as usually preceding active menorrhagia, and particularly of a more than ordinary sensation of pulse or throbbing in the situation of the uterus.

The causes of menorrhagia may be divided into the constitutional and the accidental; but it often seems to require a combination of both to excite the disease. The active menorrhagia is found to

occur in plethoric habits, often apparently as a natural relief to the overloaded system, but aggravated or excited by luxurious living, a sedentary and indolent life, hot rooms, and also by very violent exercise or any other fatiguing exertion. The passive menorrhagia, on the other hand, is caused by all those circumstances which lower the bodily powers, and weaken the action of the heart and arteries. But in both of these cases there are local causes which peculiarly tend to direct the mischief to the uterus, and increase the circulation in the vessels of that organ, leading to the increased discharge, whether that be the immediate effect of excess of activity, or diminished power of retention: such are blows and falls, or any other local violence; frequent and recent abortions, leucorrhœa, over-indulgence in sexual intercourse, irritation in the bladder, diarrhœa, tenesmus, piles, ascarides or scybala in the rectum, or even habitual or accidental costiveness.

In all severe or protracted cases, resisting the usual means of relief, it would be right to make an examination as to the actual state of the uterus itself, as symptoms closely resembling menorrhagia may be owing to organic mischief, particularly ulceration, polypus, and inversion of the womb. These causes are not immediately connected with the present article, and therefore can only be alluded to.

There is a frequent cause of menorrhagia not much attended to, and not mentioned in systematic works on the subject, but the knowledge of which is highly necessary. It has often been observed that the most obstinate forms of chronic menorrhagia occur in those persons who have an impeded or disordered circulation through the abdominal veins, particularly where there is organic or functional disorder of liver. The same cause will very frequently produce hemorrhoidal disturbances; and it is very easy to understand that the uterus in such cases will be a ready outlet for the over-distended blood-vessels of the lower part of the trunk. We have no doubt that this is not at all an uncommon cause of obstinate menorrhagia, and we are still more convinced of the truth of the opinion by the success which has often attended the adoption of a peculiar plan of treatment presently to be noticed, and which is only adapted to that condition.

Treatment.—In the treatment of menorrhagia it is especially important that we should inform ourselves as much, and as accurately as possible, of the actual state of the disease, and of the peculiar cause or combination of causes to which its origin may be attributed. It is too often the case that medical men in such instances, as a matter of course, order medicines containing infusion of roses and the mineral acids, and such-like. This is the every-day routine; and in more obstinate cases the astringent gums or metallic salts are added. But however proper such medicines may be in many, they are by no means applicable to all the cases, and much valuable time is lost by this careless mode of prescription.

In discussing the management of menorrhagia, we must bear in mind that sometimes we are called upon to arrest the violence of the discharge from the uterus at the moment, and which is occasionally so excessive as to hazard the life of the patient, unless readily restrained. We shall, therefore, in the first instance, treat of this highly necessary part of the subject, and afterwards of the mode of restoring the patient's health in the more chronic forms of the disease, and in the intervals of the discharge. In a patient who has been till recently in a robust and plethoric condition of body, and in whom the menorrhagia has been of recent origin, or has arisen from temporary and accidental causes, it will be often advisable during the actual profuseness of the discharge, to diminish the action of the heart and arteries by abstraction of blood from the arm, exactly on the same principle on which we should be led to similar practice in hemorrhage from the lungs. It is only in recent cases, however, or in very plethoric subjects, with a strong full pulse, that we may safely venture upon this plan; and then the quantity of blood abstracted must entirely depend upon the circumstances of the case, the powers of the patient being a much better guide than the severity of the symptoms. When the discharge is excessive, that alone will reduce the powers of life to so low an ebb that much additional loss of blood would be dangerous. After having abstracted blood from the arm, when the case requires this evacuation, we may proceed to the other measures, which are proper to all cases of urgent and immediate danger from menorrhagia. The free application of cold to the abdomen, pelvis, loins, and back, is one of the most powerful means we possess of restraining menorrhagia: the cold hip-bath, dashing cold water, or vinegar and water, on the person, injecting cold water into the vagina, and applying ice, both externally and internally, to the os uteri, may be had recourse to with much and often decisive advantage. It is necessary that in these cases the application of cold should not be intrusted to the nurse or attendants without the superintendence of the practitioner, as they are rarely aware of the mode in which alone the applications can be effectual. After placing cloths dipped in cold vinegar and water to the pubes, they often cover up the patient with the bed-clothes, *warm* and *comfortable*, soon converting the wet linen into a hot and reeking fomentation. Besides which, by the want of judgment, the application of cold, when properly applied in the first instance, will often become prejudicial from being continued too long. Cold is a most powerful sedative, and when the powers of life are reduced to an extreme state of exhaustion from loss of blood, it often becomes necessary for a time to reverse our treatment, and when the hemorrhage has ceased, to rouse up the sinking pulse and failing powers by the cautious application of stimuli and artificial warmth. We may do this more safely when we have made the state of the patient more secure, by another very effectual plan for restraining the hemorrhage—*plugging the vagina*. In the uterine hemorrhage which occurs shortly after parturition, this expedient is not safe; because, when the blood, by the plug in the vagina, is prevented from flowing externally, the uterus itself may again expand to a very considerable extent, from the blood being poured into its cavity; and in this way death may take place, although there is no external flooding. This can only happen, however, where the uterus

is in a condition to undergo the expansion, and in menorrhagia this is not the case. A dossil of lint, or a fine cambric handkerchief, may be gradually introduced into the vagina up to the os uteri, so as to fill the vagina firmly throughout its whole extent, and be allowed to remain there. Many prefer soaking the material previously in some strong astringent liquid, and this is, perhaps, still more efficacious. If a plug [or tampon] produce pain, it must be withdrawn; and at all events it should not be allowed to remain more than twenty-four hours, because it is apt to become very offensive and irritating from the putrefaction of the discharge. On withdrawing it, unless it be done very gently and gradually, a fresh discharge of blood is apt to be occasioned; but it can easily be restrained by another plug, or some of the other remedies.

Strong astringent injections into the vagina, consisting of solutions of alum or sulphate of zinc in infusion of galls or decoction of oak-bark, are often of service. They certainly possess great power, and act partly by coagulating the blood at the orifice of the uterus, which acts as a compress upon the mouths of the bleeding vessels. There is a remedy which is perhaps the most certain of any in restraining the discharge; but as it is not always safe, it should, in the writer's opinion, only be employed in cases where other plans less dangerous have failed — it is that of injecting the uterus itself with an astringent injection. A gum elastic male catheter is carefully inserted within the os uteri, and, by means of a syringe, a very small quantity of a solution of alum or of the acetate of lead is to be gently introduced into the cavity of that organ. Two instances have occurred, within the last four or five years, where violent vomiting was the consequence, followed by the uterine inflammation and death; and although certainly such unfortunate results of the practice are exceedingly rare, the knowledge of them must render any one cautious in applying it. Of course, where it is possible to ascertain the immediate cause of the hemorrhage, and that cause can be removed, our remedies will have but a poor chance if such a precaution be neglected. A loaded state of the rectum has been often overlooked in cases of menorrhagia, and even when recognised, many have been unwilling to produce any action of the bowels, from fear that the exertion or the disturbance might reproduce or increase the discharge. Accumulations of hard fæces in the rectum should always be removed as speedily as possible, and this may be safely and effectually accomplished by a lavement of cold water. This remedy alone, indeed, has often stopped an obstinate case of menorrhagia.

Of the internal medicines for restraining the discharge in the violent degree we have mentioned, opium and the acetate of lead are the most to be depended upon. Where the patient is much exhausted, opium may be given in large doses. Mr. Burns advises at least as much as two grains at once; and where it cannot be given by the mouth, it is to be introduced into the rectum as an injection or a suppositary. Many practitioners exhibit the acetate of lead in insufficient doses, dreading the deleterious effects which lead is known sometimes to produce in the animal economy.* When combined with opium, these effects are considered as less likely to be occasioned, and the usual practice has been to give one, two, and even three grains of the acetate of lead, with from half a grain to a grain of opium, every one, two, three, or four hours, according to the urgency of the symptoms. Dr. Mackintosh of Edinburgh has related a case (Elements of Pathology, vol. ii. p. 363) where the effects of the acetate of lead with opium were very strikingly displayed, in doses of five grains every three hours, for several successive times, without any of the signs of the poison of lead ever appearing. As opium will not always agree, and as the harmless effect of lead has been attributed to the opium being combined with it, it is very satisfactory that Dr. A. T. Thompson has lately proved that the addition of acetic acid to the acetate of lead, so as to make an excess of acid, entirely prevents the deleterious property. Other remedies have been given in the acute form of menorrhagia with success, and though not so much to be depended upon as those already mentioned, must not be lost sight of. Emetics have now and then been serviceable, but would only be safe where we wanted rather to depress the activity of the circulation. The same precaution is necessary with respect to digitalis, which has been much praised by several authors. Large doses of the nitrate of potash or of the oil of turpentine have been also highly spoken of. The most common remedies are the astringent ones, viz. kino and catechu in large doses, alum, sulphuric acid, rhatany root. Alum whey may be given as drink, or a very weak solution of sulphuric acid, made palatable with sugar.

[Many recent writers have spoken well of ergot in the dose of from five to eighteen grains, three times a day; but farther observations, as to its efficacy, are needed. The same may be said of monesia, which has been given by different practitioners in various forms of hemorrhage from the uterus. (See the author's *New Remedies*, 4th edit. p. 421, Philad. 1843.) Recently, Professor Simpson, of Edinburgh, (*Lond. and Edinb. Journ. of Med. Science*, July 1843, p. 661,) has highly extolled gallic acid, given in the interval, as well as in the flow, in doses of from 10 to 20 grains in the 24 hours, made into pills. It possesses, according to him, the advantage over most other hæmastatic agents, that it does not confine the bowels. He was first induced to prescribe it, from finding a case of very obstinate menorrhagia get well under the use of Ruspini's styptic, after many other remedies had entirely failed; and from its being alleged, that gallic acid is the active ingredient in that styptic. It has received high encomiums from Dr. Stevenson, in similar cases. (*Edinb. Med. and Surg. Journ.* July 1843, p. 183.)

The infusion of matico has very lately been given with great advantage where an internal styptic was needed. (*Braithwaite's Retrospect*, Part VI. art. 79 and Part. VIII. art. 7.)]

* Dr. Dewees states, in his "System of Midwifery," page 149, that sugar of lead has been declared a dangerous remedy, but "upon what ground we are at a loss to determine, having used it most freely for more than twenty years, without the slightest inconvenience from it." He relates a case where he gave it, as an injection into the rectum, in scruple doses.

In all these cases the most perfect quiet and the horizontal posture are indispensable.

In the more chronic form of the disease the above plans are more or less applicable, but much will depend upon the character of the individual case. When the individual is plethoric, bloodletting may be required; and in many cases Dr. Mackintosh has found advantage from the application of a leech or two to the os uteri itself. Cooling saline medicines may be taken, and the bowels kept open by saline purgatives, avoiding, however, any irritation of the canal. The infusion of roses with Epsom salts will be found one of the most useful forms of purgative, and if it irritates the bowels, henbane may be added. Cold hip-bathing, and also cold astringent injections, will be found useful. This plan, with great quiet, will be found to moderate the attack, and may be continued in the intervals; and it is worthy of remark that the next return of the menstruation may often be rendered comparatively trifling by the use of a full purgative about twenty-fours before the period, where that can be ascertained, avoiding any medicine of a drastic or stimulating quality. In these instances the diet should be very bland and spare: wine must be left off, although the common remedy in families for every sort of menorrhagia is to drink rather freely of port wine.

In the more feeble constitutions, already, perhaps, reduced by a long continuance of so debilitating a malady, besides the remedies above mentioned to abate the immediate violence of the discharge, we must endeavour in the intervals to strengthen the general frame, and restore tone to the uterus itself. But in these instances we often find it extremely difficult to restrain the discharge itself, however trifling it may be in amount. The least exertion or excitement will reproduce it, and in spite of all our remedies it continues day after day, exhausting the strength. Dr. Mason Good (Study of Medicine, vol. v. p. 66,) is of opinion that in these cases there exists a relaxed state of the solids and an attenuated state of the fluids; and certainly the discharge in nearly every such instance appears very thin, and to contain an unusual proportion of serum. Small and repeated doses of the acetate of lead are more serviceable, perhaps, than any other internal medicine, and it may be combined with opium or an additional quantity of acetic acid. The other astringents mentioned before are preferred by some authors, given in more moderate but more frequent doses. The ergot of rye, with the idea of its promoting contraction of the uterus, has been tried in menorrhagia in small and often repeated doses, and by some, it is said, with success; but others have had no reason to speak favourably of it.

In the intervals, every remedy which can give general and local power must be employed. Cold bathing, cold hip-bathing, especially, will be found of great use; and the efficacy of the water may be increased by the addition of salt or vinegar. This should be used from two to five minutes every night and morning, and a cold astringent injection should also be thrown up to the uterus. All violent exertions should be avoided, and especially shaking in an uneasy carriage, or horse-exercise. The free use of the flesh-brush will give steadiness to the circulation, and answer nearly all the salutary purposes of exercise, without the risk of mischief from too much fatigue or exertion. The diet should be nourishing, but not stimulating: fluids and the watery vegetables should be taken but sparingly, and only a small quantity of wine, of which claret or port is perhaps the best. Of medicines, the vegetable tonics are scarcely so serviceable as the mineral; but they may often be combined with advantage. The salts of iron require to be carefully administered; but in spite of their well-known effects of increasing or producing the menstrual discharge when deficient, their general tonic and astringent effect upon the blood-vessels is often exerted with marked benefit in cases of menorrhagia of the atonic character. The sulphate of zinc may be more easily managed than steel medicines, and in many instances has been more useful; from one to two grains being taken in the form of pill three times a day.

In a case of complication of obstinate skin-affection with menorrhagia, arsenic was found serviceable to the eruption, and during the exhibition of this remedy the menorrhagia ceased. This was quite accidental; but the writer was afterwards induced to try its effect in menorrhagia of the atonic character, where that was the only complaint; and the success of it has occasionally been very considerable. It has been given in doses of five to ten drops of the liquor arsenicalis, gradually increased to twenty-five, or thirty, three times a day, carefully watching the effect of the medicine, and diminishing the dose, or discontinuing it altogether, when the peculiar deleterious qualities have been evinced.

Perhaps no artificial medicines are so powerful in their action in chronic cases of menorrhagia as the natural medicinal springs, which contain minute portions of iron in solution; though some of the benefit may be fairly attributed to the change of scene and the purity of atmosphere.

In that congested form of menorrhagia which has been mentioned, accompanied by protracted intervals between the menstrual periods, much advantage is derived by abstracting blood from the uterus or from the neighbouring parts, whenever the proper day has passed over without the appearance of any discharge, and directly the sense of fulness and throbbing in the pulse is perceptible. The bowels also should be freely purged, and the feet put into hot water: in short, the treatment should be partly made up of that appropriate to cases of amenorrhea, modified by circumstances; whilst in the intervals horse-exercise and active exertion will be not at all improper but highly salutary. At the time of the actual existence of the profuse discharge, the most perfect quiet is essential, and those remedies which have been directed to alleviate the immediate symptoms.

In obstinate cases of menorrhagia, where we have reason to suspect the existence of a congested state of the liver, or an obstructed or rather a retarded circulation through the abdominal veins, before mentioned as a very common though seldom noticed cause of this disease, nearly all the usual remedies for menorrhagia will fail, and the great number of them will do absolute mischief. Although during the immediate flow of the dis-

charge, if violent, the remedies for checking it formerly mentioned become necessary, yet in the intervals we must direct our attention chiefly to the condition of the abdominal viscera. Small doses of alterative mercurial medicines, particularly the Plummer's pill, will be found very useful, and the decoction or extract of dandelion should be given in full doses. A pill of rhubarb, soap, and ipecacuanha, is a very advantageous combination to keep the bowels open, and this may be assisted, if necessary, by domestic enemata; it being of great consequence especially to prevent the collection of any hard or lumpy fæces in the large intestines. In addition to all this, the writer particularly recommends in all such cases the frequent application of a few leeches to the anus. Even in very debilitated and exhausted constitutions, this remedy, when carefully watched, may be safely administered, and relief will often be very rapidly manifested.

C. Locock.

MENSTRUATION, PATHOLOGY OF.—It is not intended in the present article to discuss the various theories of this important function of the human uterus, which have at various times prevailed. It will be sufficient to state generally that we consider the menstrual discharge to be the consequence of a peculiar periodical condition of the blood-vessels of the uterus, fitting it for impregnation, which condition is analogous to that of "heat" in the inferior animals. In Dr. Hooper's work "On the Morbid Anatomy of the Human Uterus," there is an exact representation of the uterus of a woman who was instantaneously killed by an accident during menstruation; and every one must be struck with the resemblance which it bears to the description given by Mr. Cruikshank in the Philosophical Transactions (1797) of the appearances observed by him in rabbits killed during the state of genital excitement, usually called the time of heat. The actual presence of the discharge is the *resolution*, if we may so term it, of the previous condition of the vessels which separate it; for the uterus is fitted for the purposes of impregnation before the menses begin to flow. An instance in proof of this may be given from the Philosophical Transactions (1817) of a young woman who bore two children successively without any previous menstruation; which function, in fact, did not show itself externally till after the third pregnancy, which ended in a miscarriage.

The function of menstruation lasts, upon the average, for about thirty years of the life of woman, beginning at puberty, and ending somewhere between forty and fifty years of age, unless interrupted by disease, by pregnancy, or by suckling. During this large proportion of female life there is a great liability to derangements, of one form or another, in the menstrual process; and to which much importance is attributed, though from some remains of the old doctrine that the menses were the outlets of "peccant humours," more anxiety is generally expressed in cases of diminished or suspended discharge than in those where it is unnaturally profuse. Women have also been always in the habit of considering the time of the first appearance of the catamenia, and of their final cessation, as requiring particular caution and management, and as tending to the development of a healthy or diseased condition for a long period of life. The actual flow of the menstrual discharge itself is also looked upon as a time of great delicacy, and as demanding peculiar attention; so that very few diseases can exist, and very few plans of treatment be recommended, without the presence of the menses in some way influencing the nature of the symptoms or the remedies to be applied. It is in this especially that the character of the female constitution in disease is manifested; for before puberty, and after the cessation of the menstruation, the female differs but little from the male in the character of disease, unless in those points which may be considered as accidental, such as organic diseases of the sexual organs.

In the present article we propose to consider the medical management of the female at the first appearance of the menstrual discharge, during the continuance of it, and at the final cessation.

Instances of precocious menstruation are by no means uncommon;* but occasional discharges of blood from the vagina of young children cannot be considered in this light, unless accompanied by the usual signs of puberty. Precocity must always be considered relatively as to climate, for the difference in hot and cold countries is very great. Dr. Denman has quoted an opinion of Hume (the historian), which is scarcely borne out by facts; the difference in the time of life when the menses appear being assigned as the reason why women in hot climates are almost universally treated as slaves, and why their influence is so powerful and extensive in cold countries, where personal beauty is in less estimation "In hot climates, women are in the prime of their beauty when they are children in understanding; and when this is matured, they are no longer objects of love. In temperate climates, their persons and their minds acquire perfection at, or nearly at the same time, and the united power of their beauty and faculties is supposed to be irresistible." (Introduction to the Practice of Midwifery, p. 83.) The influence of civilization seems to have been entirely overlooked in this theory; as otherwise the most chivalrous devotion to the fair sex would be found in the savage inhabitants of the countries of perpetual snow. Precocious menstruation can scarcely be considered as a disease, but it certainly is not desirable, for many obvious reasons; and as artificial circumstances may hasten it, avoiding such causes or counteracting them may not only prevent, but may even supersede it. For example, cases have been related in which girls have menstruated, with all the signs of puberty, at nine or ten years of age, in the East Indies; and having been removed to Europe, the function has ceased, without disorder of the health, and has not appeared again till the age of fourteen or fifteen, at which it usually comes on in this country. Hot and crowded rooms, luxurious habits, early excited passions, and improper indulgences, are well known to promote an early development of sexual power, and should be carefully counter-

* We refer in particular to a case by Dr. Wall, of Oxford, in the second volume of Medical and Chirurgical Transactions.

acted in those cases which seem to call for interference. An opposite condition to precocity is also very commonly met with; but however late the period may be at which menstruation first comes on, it is not a disease in itself, so long as the symptoms of puberty are not manifested. The parents of a young woman are often anxious upon this point, and request medical aid to bring on the menstruation; but, unless by attending to the general health, the practitioner is not justified in interfering. In some unfortunate instances, the signs of puberty never come on, from some organic deficiency in the genital organs, particularly the ovaria; and all attempts to excite a menstrual discharge would be pernicious.

For a very considerable period before puberty, often two or three years, symptoms of the approaching important change in the system may be detected. It is not at all uncommon to meet at this age with very obstinate disorders, such as headachs, epileptic fits, or cutaneous affections; and upon finding the usual plans of treatment fail, medical men are in the habit of prophesying a cure when menstruation is established: this arises from long experience of the frequent truth of such a result. As the time draws near, the system becomes more irritable; there is a general uneasiness, and an alteration of the moral character; there is also very commonly much languor, flushing, sensation of fulness, headach, livid marks round the eyes, disordered appetite, impaired digestion, and disturbed or unnatural heavy sleep. These symptoms continue for a longer or shorter period; and immediately preceding the first appearances of the discharge, there is much pain and weight, with fulness in the head and pelvis, and throbbings and swelling of the mammæ. Although the actual discharge is rarely quite regular to the month for the first half year or so, passing over a month or two, yet the usual constitutional symptoms just enumerated as directly preceding the discharge are found to observe the lunar intervals and to be aggravated monthly, even for some time before the flow of the menstrual evacuation itself. With many, the symptoms above mentioned are either so slight or so temporary, that no great attention is paid to them. Where medical aid is required, the plan of treatment must depend a great deal upon circumstances; as a general rule it is best to temporize, knowing that a little patience will carry the patient to the termination of the discomfort. Should there be any very great disturbance, with a full pulse and much headach, the abstraction of a small quantity of blood will be prudent. The diet should be carefully regulated, and abstinence from meat or wine strictly enjoined. The bowels should be kept rather more open than usual, but not with any of the more irritating and drastic purgatives, under the idea of exciting the uterus to action, as is too commonly recommended; the object being to lead the patient through the struggle without any force or disturbance. We should watch excess of action of every description, and restrain it, but not attempt to stimulate any apparent deficiency, unless actual disorder of health be manifested. Circumstances may arise, however, to call for more decisive measures; and the menstruation may be so protracted as to constitute one of the forms of *amenorrhœa*, the nature and treatment of which have been detailed elsewhere. (See Amenorrhœa.)

During the menstrual period, when quite regularly and properly performed, no medical treatment is required; but it should never be lost sight of, either by the patient herself or by her medical attendant, in case of any accidental illness, or any general plan of management of the health. Women expect this carefulness, from the great importance they habitually attach to the proper performance of the function; and therefore, in prescribing for females, it is always right to inquire as to the expected time, as well as the regularity of the periods, to guide us as to the propriety of continuing or remitting any part of the remedial measures. There are many things to be guarded against on these occasions which might be safely followed at any other time; and while much depends on the patient's own prudence, still the physician is constantly blamed if he lose sight of the necessary precautions. It is necessary to avoid any very active purgative medicines during menstruation, particularly those which irritate the lower part of the rectum, as they are apt to produce a morbid increase of the discharge. Medicines containing the preparations of iron, strong diuretics, emetics, myrrh, or mercury, are usually ordered to be suspended during the periods, although it is very doubtful whether the milder mercurial medicines in gentle doses can be productive of mischief. Cold bathing ought also to be discontinued, particularly the hip and foot baths; and yet it is a well-known fact that the dippers attached to the bathing-machines at the sea-side are in the habit of being for several hours in and out of the sea during the catamenial flow without detriment. Wetting the feet or exposure to rain under these circumstances has now and then suddenly suppressed the menstruation, and brought on illness of an alarming nature. Dr. Dewees states that in America it is not at all uncommon for young girls, bent upon a party of pleasure, to put the feet in cold water to stop the discharge. It need scarcely be stated that all vaginal injections to restrain leucorrhœa must be left off at these times. Any very violent exercise is to be carefully avoided during menstruation: partly because it is very apt to produce too profuse a discharge, and partly because, on account of the increased weight of the uterus and relaxation of the vagina, a serious degree of prolapsus uteri has been often occasioned by it. Some aggravated instances of this distressing complaint, even in unmarried women, have occurred in the writer's own practice, which have been brought on by dancing, by horse-exercise, and by over-fatigue in walking, during the menstrual period.

The Jews, and even more modern nations, believed that there was something deleterious and contaminating in the menstrual discharge itself; and hence various directions and regulations as to seclusion and cleanliness of person. It is not necessary now to controvert these doctrines, but it were well, perhaps, if more strict attention were to be paid to some part of the regulations even in the present times. Either by accident or by criminal impatience, sexual intercourse has sometimes been permitted during the period of

menstruation; and, although not constantly, yet such conduct has been frequently followed by the most serious effects—generally by profuse hemorrhage; at other times by a sudden suppression of the discharge; to which have succeeded fever, delirium, obstinate hysteria, confirmed mania, and even catalepsy. (See AMENORRHŒA.)

When the function of menstruation has been once fairly established, it may become disordered in several ways, each forming distinct classes of diseases. Menstruation may be faulty in respect to the quantity of the discharge, the quality of the discharge, the regularity of its appearance, the time of its duration, and the degree of pain with which the process is accompanied. When the discharge has been in any way suppressed in a peculiar condition of health, what has been called *vicarious menstruation* has sometimes periodically occurred from other parts of the body, the stomach, the lungs, the bowels, &c., although Dr. Dewees evidently doubts the existence of such anomalies. For a minute account of these several forms of disordered menstruation, the reader is referred to the articles AMENORRHŒA, DYSMENORRHŒA, and MENORRHAGIA.

During pregnancy and suckling, menstruation ceases. This is undeniably the general rule. Under the head of LACTATION, the exceptions to this law of nature, as regards *suckling*, have been noticed, and no one perhaps will deny their occasional occurrence. But many practitioners of extensive experience in midwifery have denied the possibility of menstruation going on during pregnancy, and declare the supposed cases to be either false altogether, or that the discharges which do sometimes occur during pregnancy are not menstrual, but are irregular in time, sparing in quantity, and sanguineous in character. They rest their arguments upon the fact, that at a very early period of pregnancy the os uteri is closed by the thick glutinous secretion which is poured out by the glands at the cervix; and also, that from the interior of the uterus being coated with the decidua vera, there is no surface from which the menstrual fluid could be secreted. Many experienced medical men, and women themselves in general, believe not only in the possibility, but in the comparative frequency of menstruation during the first three or four months of pregnancy; and Dr. Dewees mentions a case in which he was firmly convinced that it went on regularly to the *seventh* month, lasting three or four days, exactly as usual, not sanguineous, at least not containing perceptible coagula, and only differing from common periods in being less and less abundant as the pregnancy proceeded, after the fourth period. The first argument, as to the impossibility, is scarcely tenable, when we recollect how readily slight hemorrhages find their way through the os uteri in spite of its closure, from some accidental disturbances of the ovum at any period of pregnancy, without being followed by miscarriage; and if such discharges can escape, why not the menstrual? In reply to the second, Dr. Dewees asserts, that as menstruation occurs from the cervix uteri in the unimpregnated uterus, as well as from the body and fundus, there is sufficient space for some menstrual fluid to be secreted in that part of the cervix which remains uncovered by the deciduous membrane, and, as is well known, is not taken up into the body of the uterus till an advanced period of pregnancy. He states that a very small space will be sufficient for the purpose, as was proved by discovering in a post-mortem examination that the uterus of a young woman who had menstruated quite regularly and properly to the time of her death, retained only a surface healthy enough to perform the menstrual function, of the size of the finger-nail, all the rest of the interior being in a state of disease. In stating the opinions on both sides, it will be scarcely necessary to advert to our own; but, although firmly convinced that a perfectly regular discharge as to period is not uncommonly found to continue for the first two, three, or four months of actual pregnancy, yet we do not therefore conclude that such discharge necessarily comes from the uterus, or is exactly menstrual. In what the difference consists between the menstrual fluid and blood is not accurately known; that it does not coagulate is not saying much, as the blood of persons affected with scurvy, or of those killed by lightning or by some of the powerful narcotic poisons, does not coagulate; and menstruation is rarely very profuse without coagula being also expelled, no other secretion ever containing pure blood mixed with it, unless from organic lesion.

From habit, there is a tendency of the circulation towards the uterus every month, even during pregnancy; and few women are found who do not experience the symptoms occasioned by it, for the first month or two: hence it is that miscarriages are so apt to occur at those periods at which menstruation would have appeared, had not the process been interrupted by pregnancy; and hence, also, a periodical relief resembling menstruation may occur for the first few months, the blood-vessels at the cervix uteri, or the upper part of the vagina, giving way for the purpose. When this occurs, as it is unnatural, and might lead to abortion, great care is required; and when patients have shown a tendency to it, they should be kept in the horizontal posture for a few days, and a few ounces of blood be abstracted from the arm, or, by means of leeches or cupping, from the neighbourhood of the uterus. Although it is not pretended that these cases are common, and they can only be regarded as exceptions to a general rule, yet it is important that no one should blindly deny their possibility, since it might lead to a neglect of those precautions which pregnancy requires.

The important period of the cessation of the menses is liable to the same varieties as that occasionally observed on the first appearance, and is also accompanied with many very striking changes in the animal economy. It is an age which is always looked upon by the female sex with a certain degree of apprehension, as one in which the foundation is often laid of many a painful and dangerous malady; and yet those who previously are suffering from long-continued general illness or any obstinate chronic disease, are accustomed to look forward to the time when the constitution shall become *settled*, as it is termed, for a relief to their sufferings and a restoration to more perfect health. When the uterus is no longer in a condition to perform the function of menstruation, the

power of conception also ceases; and it has been considered by some authors that this was a wise ordination to prevent women from becoming mothers at so advanced an age that they would be incapable of properly attending to their offspring while still too tender to provide for themselves. As it has been generally acknowledged that the uterus is most fitted for impregnation directly before or after each menstrual period; so it also happens, that for a short time before that process ceases for ever, there appears to be an unusual degree of stimulus in the generative faculty; and many women who have ceased to bear children for years, or who have been hitherto barren through the whole of their married existence, at this time, to the surprise of their friends and of themselves, become pregnant. Still more commonly, however, does it happen that women mistake their condition under these circumstances, and so obstinately believe themselves pregnant, that it becomes exceedingly difficult to convince them of their error. It is easy to suppose that at this particular age such mistakes are likely to arise, for the symptoms that naturally accompany the cessation of the function much resemble those of pregnancy. Women are unwilling to be thought beyond the age of bearing children, and are perhaps on that account misled by their wishes; but they not unreasonably are struck with the first sign which generally occurs,—namely, the passing over of the menstrual period; and their attention is ready to seize hold of every flattering explanation of the circumstance. Other symptoms are soon manifested; the size increases, the breasts even become swollen and painful, the stomach disordered, and the appetite capricious, so that a pregnancy sickness is not uncommon; flatulence collects in the intestines, and whilst on this account the size still increases, the sudden motions and rolling about of the confined air are mistaken, even by women who have previously borne many children, for the plunging of a fœtus. It is only by time, or by an examination per vaginam, that the mistake is detected, much to the annoyance of the patient and her friends; but the symptoms are easily removed by the free exhibition of carminatives and purgatives, the use of active exercise, and bandaging the distended abdomen, which has probably been allowed more room to expand than formerly, from a fear of tight lacing in pregnancy.

In this country the average age at which women cease to menstruate, or "*the time of life*," as it has been called, is forty-five. Where they have begun early, it generally ceases early; and, on the other hand, where they have begun late in life, it often lasts much later than common. Some women have ceased entirely before the age of thirty; others have gone on to nearly sixty, or even beyond this period. Many of the cases, however, which have been related of women who have continued to menstruate till seventy, eighty, or upwards, or who have begun again ten or fifteen years after having apparently left off for ever, were not genuine cases of menstruation, but sanguineous discharges, generally irregular, and arising from some disease of the uterus.

Menstruation ceases sometimes at once, when the female has arrived at the usual age; but this rarely happens, unless accidentally, as it may be termed. For instance, something or other takes place to check the expected discharge, which would have had the same effect at a much earlier age, such as cold, fright, some acute illness, or any other fortuitous occurrence. At any earlier period the menstruation would return on the cessation of the illness; but now it seems to take the opportunity of departing without further trouble, and never again appears. Much more frequently the change is gradual, and accompanied with such irregularities that it has not inaptly been called "*the dodging time of life.*" The quantity varies much as well as the regularity of the return; sometimes for two or three successive periods it is extremely scanty, and then suddenly is so profuse as to partake of the character of uterine hemorrhage, and even to create alarm as to the immediate result. The discharge sometimes returns every two or three weeks, and then ceases for several weeks, or even months, and afterwards perhaps for a time recurs as regularly as usual. In females in whom it has been always previously the most regular, and when the person has been uniformly healthy and of temperate habits, the cessation of the function goes off the most quietly, and with the least subsequent derangement of the system. Many, however, who have not been so fortunate in their state of health, by being carefully conducted through this critical period, have apparently renewed their existence, have lost their previous delicacy of constitution, and become more healthy than ever; so that it has been remarked that their lives are likely to be prolonged to a more advanced age than men of equal standing and at the time of equal health.

But this is the most favourable termination of the period; for with many it is only the beginning of a train of great suffering and of constant illness, ending in an early death.

[It would not seem, however, that this *critical age, critical period*, or *critical time of life*, as it has been termed, is so full of danger as the epithet 'critical' might suggest; for the statistical researches of De Chateauneuf, and of Lachaise, Finlaison, (*Reports on the Evidence and Elementary Facts on which the Tables on Life Annuities are founded*, Lond. 1829,) and others, have shown, that between the ages of forty and fifty no more women die than men. (D. Davis, *Principles, &c. of Obstetric Medicine*, i. 290, Lond. 1836, and Desormeaux and P. Dubois, in *Dict. de Méd.* 2d édit. xix. 467, Paris, 1839.) M. Constant Saucerotte has, indeed, attempted to establish, by statistics on a great scale, that the mortality amongst women is greater between the ages of thirty and forty than between forty and sixty; and Muret, in his statistics of the Pays du Vaud, did not find between forty and fifty a more "critical" age than between ten and twenty. (Churchill, *Outlines of the Principal Diseases of Females*, Prof. Huston's edit., Philad. 1842.)]

Whenever there is any tendency to organic disease, or any weak point in the frame, this is the time when the mischief becomes manifest, and the symptoms are first detected. It is not, as Dr. Dewees has very properly remarked, that the particular diseases are caused by cessation of the menses, but the seeds of such affections already

existing are roused into activity by the changes which take place in the system at that period. For perhaps thirty years of the woman's life there may have been an habitual monthly discharge of from four to six ounces, more or less, of a secretion which is nearly allied to pure blood, from the uterus; and it is not surprising that, on this being stopped, the long habit should produce a tendency to the same relief every month; which not taking place, the excess is thrown back upon the circulation, and local congestions are the consequence. Even under the most favourable circumstances there are symptoms of congestion, shown by headach, shortness of breathing, oppression at the præcordia, and a tendency to corpulency. But whenever any organ is in a state of disease, however latent hitherto, the redundancy is thrown especially to that quarter, and the disease is rapidly called into activity.

It is not surprising, from the great alteration which takes place in the organs connected with the function itself, or those which have been particularly affected by it, that they should be the parts most liable to become diseased at this time; and certainly most organic diseases of the uterus and mammæ date their perceptible origin from this period. Besides cancerous tumours, medullary sarcoma, hæmatoma or fungus hæmatodes, attacking the uterus and breast, many serious diseases of other parts often arise. Apoplexy is not an uncommon occurrence, but is not so often fatal at this age as at one more advanced. Organic disease of the liver or of the other abdominal viscera is much more common than of the lungs, the abdominal circulation being perhaps more closely influenced by the want of the uterine secretion. Very obstinate disorders of the skin frequently make their appearance at this age for the first time, producing great distress and disorder of the health. There is sometimes an apparent effort of nature to substitute some other discharge as a compensation for the one which has been suspended; and it is right always to respect these contingencies, as, however disagreeable they may be, the removal or cure of them may be dangerous. Leucorrhœa is a very common instance of this natural relief; and discharges of blood from the hemorrhoidal veins is another, which now and then becomes periodical. Ulcers sometimes form and discharge copiously, on the legs or behind the ears, and should not be carelessly healed, unless other measures are taken to prevent mischief.

The medical management of the important period of cessation of the menses may be easily collected from what has been already remarked. Recollecting the condition of the system, particularly of the circulation, it will be necessary to keep it free from disturbance as much as possible, to relieve any organ or part of the body which may appear oppressed or in a state of congestion, and to watch carefully the first threatenings of any local disease. Should the pulse be full and hard, and should there be any general plethora, frequent small bloodlettings will be advisable. Every local pain, heat, or sensation of fulness, should be relieved by leeches or cupping. The bowels should be kept carefully and freely open by purgatives which do not irritate, but which produce watery motions, such as the neutral salts or castor oil. If the pulse is habitually quick and hard, small but repeated doses of mercurial medicines may often be of service, and remove any obscure inflammatory action which may insidiously be going on. The diet should be mild, and moderate as to quantity, meat and wine either omitted or but sparingly allowed. Exercise must be regulated by the circumstances of the case; it is very desirable where no local mischief appears to exist, as it promotes regularity of action and general health; but otherwise great quietude should be observed. The production of artificial discharges by means of issues, setons, or perpetual blisters, so much in vogue formerly, is now no longer fashionable, from the dislike patients have to such remedies; but viewing what is often effected naturally, we cannot doubt but that their more frequent employment would be highly advantageous.

In some peculiar constitutions most of the disturbance consequent upon cessation of the uterine functions seems to attack the nervous system, and hysteria, epilepsy, or mania sometimes takes place. The management of such cases requires some modification in the treatment above recommended: conium has been found of great service by some; and now and then even mild tonics are required to steady the irritable condition of the frame. When such diseases arise for the first time at this period of life, they generally prove obstinate, and often incurable. Some have proposed to attempt to reproduce the menstruation, as a means of relief when any of the formidable disorders above mentioned come on, by the employment of violent remedies of the emmenagogue class; but this practice might be highly dangerous, and probably excite uterine diseases of the most fatal description.

[MENTAGRA. See Sycosis.]

MESENTERIC DISEASE. See Tabes Mesenterica.

MILIARIA.—This term, derived from *milium*, a millet seed, is applied to a minute vesicular eruption which occasionally appears in the progress of various acute disorders, the vesicles resembling in size and colour the seeds of the millet plant.

It has been regarded by some authors as an idiopathic eruptive fever, to which the name *miliary fever* has been given. By many of the older writers it has been confounded with scarlatina and rubeola; and from its having been occasionally observed to co-exist with purpura, the idea probably first originated that it was only a modification of this eruption. We have also on record several accounts of an epidemic miliary fever,* which has at various times prevailed, though it is evident that the eruption was only an accidental or symptomatic affection, and as little entitled to characterize an epidemic as petechiæ that appear in some epidemic fevers, and from which the disease has been termed *petechial* or *spotted fever*.

The miliary eruption appears in the form of small round vesicles about the size of a millet-

* *Pujol*, Mém. sur la fièvre miliare qui régna en Languedoc et dans les provinces limitrophes, durant le printemps de 1782. *Rayer*, Histoire de l'epidemic de suette miliare qui a régné, en 1821, dans le département de l'Oise.

seed, surrounded by slight inflammation. It is most abundant on the neck, breast, and back, but is less copious on the face and extremities, and sometimes comes out in irregular patches, frequently appearing and again disappearing without evident cause. The vesicles are at first so exceedingly small that they can hardly be distinguished except by their roughness: when examined through a lens, the round, vesicular form of the eruption (each vesicle containing transparent lymph) is distinctly visible, though, from the red colour of their under-surface being transmitted through the transparent pellicle, they are of a red colour; the lymph, however, becomes, in the course of twenty-four or thirty hours, opaque, and thus gives a pearly white appearance to the eruption. From this evidently originated the two varieties mentioned by the older writers; the *red* and the *white* miliaria, (*rothen friesel* and *weisse friesel* of the Germans,)—a distinction not only unnecessary but unfounded, as it is apparent that both these supposed varieties are only different stages of the same eruption.

Miliaria is sometimes rapid in its progress, and the eruption copious and generally diffused: in other instances it is partial and slow, and though the vesicles are usually distinct, they sometimes cohere and become confluent, and thus assume the form of phlyctenæ or small bullæ.

Its duration is various: it sometimes passes off in a day or two; the vesicles either breaking, or the lymph being absorbed, slight desquamation of the cuticle terminates the disorder. According to Bateman, it frequently lasts from seven to ten days, and sometimes much longer: indeed, under the treatment formerly pursued, when the sick, according to the expression of Blackmore, lay "drowning in sweats," it was not uncommon for crops of vesicles to be renewed a second, third, or even a fourth time, and the whole disease to be protracted to nearly fifty days.

The only disease with which miliaria can possibly be confounded is *eczema*. From this it may be distinguished by its being invariably symptomatic of some acute febrile disorder, and by its rapid progress and short duration. Besides, in *eczema* the vesicles are usually confluent, and confined to a circumscribed or limited space, whilst in *miliaria* they are generally distinct, and much more numerous.

With regard to the diseases in the progress of which miliaria occasionally appears, we may observe, that since the introduction of the cooling regimen which now forms an essential part of the treatment of every variety of febrile disorder, it is comparatively rarely met with. In common, continued fever, even in the worst forms of it, when judiciously managed, its appearance is almost unknown. We cannot bring to our recollection a single instance out of the numerous cases which we have had under our care in the Fever Hospital, though we have had repeated occasion to observe it in the crowded, ill-ventilated apartments of the lower orders, when ventilation has been unattended to, and a stimulating regimen adopted.

Miliaria is more apt to appear among women after delivery than in any other circumstances. So frequent, indeed, was its occurrence half a century ago, that it was described by some writers as an epidemic among lying-in women. From the accounts given of the management after delivery, by those who witnessed it at the period referred to, there can be no question that the eruption was induced by the injudicious mode of treatment adopted. In later times, since the adoption of a more cooling plan of management after delivery, not only are febrile disorders less frequent and violent, but the miliary eruption is seldom observed; and when it does occasionally appear, its origin may be always traced to an over-heated atmosphere, over-loading the patient with bedclothes, and the stimulating regimen adopted by the poorer classes, under the mistaken notion that the parturient female may be thus prevented from *catching cold*. Miliaria is also a frequent accompaniment of the milk-fever, and of ephemera or weed, when the perspiration is injudiciously encouraged. Dr. Burns thinks that this is by far the most frequent form under which the miliary rash appears, but he states that it is sometimes observed in women who have been much reduced, but who are free from fever.

With other fevers, Bateman remarks, in which a similar method of treatment was pursued, though in a less degree, and the patient was confined to bed, the miliary eruption, with its attendant languor and exhaustion, was frequently conjoined, especially with catarrhal and rheumatic, and also with typhoid, remittent, and intermittent fevers. Whence the writers who have described the miliary fever, speak of it as being disguised under, or counterfeiting the characters of these fevers respectively. In the summer, indeed, when ventilation and coolness are not sufficiently attained or attended to, a slight miliary eruption is even now occasionally seen; a miliaria *clinica*, in fact, may be thus induced by any circumstance that confines a person to bed; as an accident, or a surgical operation, an attack of hysteria, a state of asthenia, &c. From the increase of cutaneous heat, connected with the exanthematous fevers of the nosologists, some degree of miliaria is liable to occur in them all, but more especially in scarlatina; and a few larger pearl-coloured vesicles also occasionally appear. (Practical Synopsis of Cutaneous Diseases, p. 245.)

The miliary eruption does not afford any relief to the symptoms of the disease on which it supervenes: it is generally preceded by an increase of the fever, and a sensation of heat, pricking, or tingling of the skin. A peculiar acid smell of the perspiration is also perceptible, though we apprehend, from this fetor of the perspiration being frequently noticed in various forms of fever in which there is no cutaneous efflorescence, its connection with the eruption is not satisfactorily established.

Though there be no proof of miliaria being contagious, several attempts to induce the disease by inoculation having failed, it is affirmed by Frank, (De Cur. Hom. Morb. Epit. tom. iii. sect. 322,) and other writers, to be often epidemic, and in some localities endemic. Rayer has given an excellent description of an epidemic miliaria, attended with symptoms of a malignant character, which proved in many instances rapidly fatal. From the account given by this writer, it seems to have prevailed epidemically, chiefly in Picardy,

Languedoc, and Normandy; but it is so little known at Paris, that many physicians have expressed their doubts of the reality of such a disease. From observations made during epidemic visitations, it appears that no age is exempt from it, though the greater proportion of cases occur in adults, and that females are more frequently the subjects of it than males.

In the epidemic which prevailed in the autumn of 1821, in the departments of the Seine and Oise in France, and which was very fatal, we are told by Rayer that the eruption was preceded by feverish indisposition accompanied by copious perspiration, which continued throughout the progress of the disease.

The eruption appeared generally about three or four days afterwards, first on the neck or around the ears, and spread to the chest and back, and thence over the abdomen to the inferior extremities. The rash was sometimes generally diffused; in other cases it was only partial; the vesicles being distinct, small, and diaphanous, though sometimes large and confluent, so that on some parts of the body large bullæ appeared. The odour of the perspiration was often extremely fetid, which continued in general during the progress of the disease.

The disorder was in many instances mild, but in the more severe cases inflammation of the mucous membrane of the intestines, or of the lungs, or of the brain or its membranes, supervened, and rendered the disease more dangerous.

Its duration was various. The more severe cases often terminated fatally within twenty-four or forty-eight hours. In the milder cases, it sometimes disappeared in eight days; more generally, however, it was protracted to the end of the second week, and sometimes lasted three weeks.

[One of these epidemics occurred in 1837, and another in 1841 and 1842. In one part of Dordogne, according to a report made to the *Académie Royale de Médecine*, by MM. Rayer and Bricheteau, of a population of 82,200 persons, 10,400 were attacked by the disease, of whom 800, or one in thirteen, died.]

Treatment.—From what has been stated of the nature of miliaria, it is evident that it is to be regarded only as a symptomatic affection. Free ventilation and a cooling regimen constitute not only the best means of preventing, but of removing the rash; therefore when it supervenes on acute diseases, the cooling antiphlogistic treatment is to be pursued. For this purpose the chamber is to be duly ventilated; the linen of the patient changed as often as circumstances permit; the thirst abated by cooling subacid drinks; the bowels regulated; and the diet should be of the mildest kind. Tonics have been often found beneficial, and none are better than the mineral acids—as the diluted sulphuric or oxymuriatic, which may be taken at intervals. When miliaria occurs as an epidemic, the same treatment has been successfully pursued; and when complications arise in the progress of the disorder, the particular local affection must be treated on the principles already fully detailed in the article Fever.

[The epidemic of Dordogne, referred to above, was found to prevail most in marshy situations, and to be treated most satisfactorily in the same manner as intermittent fever, by sulphate of quinia, and other tonics; particular care being taken not to interfere in any manner with the progress of the miliary eruption.]

A. Tweedie.

[MILK FEVER. See Lactation.

[MILK SICKNESS.—Under another head, (Art. Fever, Continued, vol. ii. p. 183,) a disease was referred to, which was, at one time, ascribed to a plant called by the natives of Tennessee *Indian hachy*. The vegetable poison was presumed to enter the circulation, without necessarily inducing injurious effects on the animal, but afterwards causing fever and even death in those who used its milk. Of late, many inquiries have been made into the nature and causes of this disease, which has also received the names of *trembles* and *sick stomach;* but we hear no more of its being occasioned by the vegetable above mentioned; whilst it has been ascribed to other plants—the *rhus radicans*, or *rhus toxicodendron*, for example, (J. J. McIlhenny on *Milk Sickness*, Springfield, 1843); and even to arsenic in the soil, (J. S. Seaton on *Milk Sickness*, Louisville, 1841.)

The discrepancy, amongst observers, as to its nature is indeed, surprising; some denying that it is a distinct disease, and regarding it as a form of gastro-enteritis (N. Crookshank); others considering it to be nothing more than an autumnal fever of a congestive type, attended with great irritability of the stomach. Thus far, the causes would seem to be wholly unknown; (J. Travis, *Western Journal of Medicine and Surgery*, Aug. 1840; G. B. Graff, *Amer. Journal of the Med. Sciences*, April, 1841, p. 351;) but, according to Professor Drake, (*Western Journ. of Medicine and Surgery*, Nov. 1841, p. 370,) in the state of Ohio, transforming the surface of the infected districts by the hand of art has been found infallible.

In man the disease is generally believed to be induced by using as diet the flesh or milk of animals infected with it; and it is affirmed by Dr. Graff, that butter and cheese, manufactured from the milk of a diseased animal, are the most concentrated forms of the poison, although they may possess no appearance, smell or taste, which distinguishes them from the healthy article.

It is affirmed by Professor Drake, that undue importance has been attached to the disease. The mortality from it, he says, is very small, compared with that from many other maladies, about the causes of which few inquiries are made. "There can be no doubt, that more persons annually die in the west from autumnal fever, than have died from milk sickness from the commencement of its settlement. Even in the districts where the disease is endemic, it does not destroy as many as pleurisy or cholera morbus."

The most appropriate treatment has been that adopted in remittent fever, modified according to the special indications.

Robley Dunglison.

MIND, ALIENATION OF. See Insanity.]

MIND, SOUNDNESS AND UNSOUNDNESS OF. (As a treatise on Mental Derangement is incomplete without a consideration of various medico-legal questions connected with that subject, it may be thought that the contents of the present article should have been comprised in the former one on *Insanity*. The reader will perceive that the subjects now entered upon are treated in a more comprehensive manner than such a connection would allow. Under *Unsoundness of Mind* are comprised several defective states which do not come under the head of Insanity. For this reason it is more consistent with propriety and distinctness of arrangement to take up the consideration of all these subjects in a separate article, for which no more suitable inscription could be devised than that here adopted.)

What constitutes soundness and what unsoundness of mind? In other words, by what distinguishing circumstances are we led to pronounce as to the presence or absence of such a state of the mental faculties as renders a man incompetent to the management of his affairs, and absolves him from moral responsibility? Is this state of the understanding absolute, and, if it exists at all, extending to all cases and varieties of circumstances, or does it admit of degrees and modifications? Of these and several other subordinate questions physicians are liable to be called upon for a solution, and for such a solution as may facilitate the judgment that is to be formed in particular instances; in those especially which present circumstances of unusual doubt and perplexity. The conditions on which depends unsoundness in the mental faculties are various disorders or defects in the functions or structure of the brain. With such states of that organ, and with their manifestations, persons who profess the study of medical science are supposed to be conversant. They are accordingly expected to supply information as to the nature of such affections, their extent and duration, their distinguishing characters and ultimate results. The general facts and references which are applicable to these subjects constitute a part, and by no means an uninteresting division, of medical jurisprudence. This department of legal medicine may be said to comprise all that may tend to elucidate the various questions which arise in connection with mental disorders and defects; in the first place as to the relations which persons labouring under them bear to human society, and the alteration both in respect to rights and responsibility which arise from the circumstances of their state; and, secondly, as to the modes of proceeding which are requisite, in order as far as possible to secure such individuals and others from the injurious results connected with the peculiar condition of the former.

It is remarkable that our medical literature is particularly defective in respect to this branch of professional inquiry. Except the short treatise of Dr. Haslam, which is doubtless well known to our readers, we have scarcely anything in the English language expressly relating to this subject; and Dr. Haslam's work, although it displays in some striking remarks the strong sense which distinguishes the author, is much too limited in its scope and too discursive to furnish all the assistance which is required. By some German and French writers the subject has been treated in a more systematic and comprehensive manner. In the various works of Metzger, Heinroth, Reil, and Hoffbauer, and in particular treatises and occasional commentaries by MM. Esquirol, Georget, Marc, and others, almost every topic connected with the inquiries above defined has been considered and discussed, under the several relations of which it is susceptible; and from the different points of view selected by these writers, much information may be obtained. We shall endeavour to afford our readers, such of them at least as are not conversant with the original authors, an opportunity of estimating the value of these researches by laying before them in a short space a general survey of their results.*

By the writers above mentioned, the subjects of lunacy and mental incompetency have not been considered principally with reference to specific enactments or the decisions of lawyers in any particular country. This, indeed, is not the point of view in which such questions will be most properly contemplated by physicians. It is the business of medical writers to record facts as they present themselves to the observer of nature, and to found on a correct statement of facts such results as common sense, aided by the habit of reflection on similar topics, may enable them satisfactorily to establish. When this shall have been accomplished in a manner unexceptionable and commanding general assent, legal regulations must, and no doubt will, sooner or later, be made to accommodate themselves.

Of all the works on this subject with which we have any acquaintance, the treatise of Professor Hoffbauer is the most comprehensive; displaying at the same time the results of calm reflection, and long and extensive observation on the questions to which it relates. We shall, in the remarks which we have to offer, follow the plan of this writer, and take up the different points which offer themselves to our consideration nearly in the order in which he has surveyed them.†

The Roman law and the code of Prussia specify, incidentally, various defects and disorders of the mind, and in the latter compilation the terms employed are in some instances defined. The French code, in the opinion of Hoffbauer, has adopted a course which indicates the good sense of the legis-

* It should be mentioned that a large portion of Dr. Conolly's Inquiry concerning the Indications of Insanity is devoted to this particular subject.

† Herr Hoffbauer was not a practical physician, but a doctor of laws and professor in the University of Halle, who made psychology and diseases of the mind the particular subject of his studies. He is the author of several works on insanity and the inquiries connected with it. The first, entitled "Untersuchungen über die krankheiten der Seele, u. s. w." was published in 1802–1807. He afterwards published, in conjunction with Reil, the celebrated author of Researches into the Structure of the Brain and Nerves, a work entitled "Beyträge zur Beforderung eigner kurmethode auf psychischen wege." His most popular work, entitled "Die Psycologie in ihren hauptanwendunden auf die Rechtspflege nach den allgemeinen gesichtspunkten, &c." has been translated into French, with notes by the editor, M. Chambeyron, and additional comments by MM. Esquirol and Itard. Professor Hoffbauer shows, in many instances, a want of practical knowledge of insanity, but he has discussed admirably the legal relations of mental deficiencies. A critical analysis of his works has been given by Professor Heinroth, in his "Lehrbuch der Störungen des Seelenlebens," th. 2.

lator: it makes occasional references to the various classes of affected persons, whose states are distinguished respectively by the terms of Madness, Dementia, and Imbecility; but it nowhere determines the precise import of these expressions. "In fact all legislation ought to be founded on the knowledge of the objects to which it is applied; but this knowledge failing, it is better that the law should not define, than that it should define erroneously, and thus introduce errors which would only be perpetuated by its authority." The triple division which the French code recognises corresponds with facts, and with the actual distinctions of nature. In reference to mental disorders and defects we distinguish three very different states, involving mental incapacity. These are, *idiotism* or *congenital weakness* in all its degrees, depending on an originally imperfect formation or development of the brain; secondly, *insanity* in several forms; thirdly, *dementia* or *intellectual decay*. This last state, though considerably varied in particular modifications, is most frequently a permanent failure of the mental powers; it is the result of long-continued insanity, of old age, when life is protracted beyond its natural period; sometimes it ensues on apoplexy or paralysis, or on repeated and severe attacks of epilepsy: in other instances it appears as the sequel of fever attended with delirium; and in these last cases alone it often terminates in the recovery of health and a sound state of the mind.

The distinguishing characters of *dementia* have been described in the article Insanity, and we shall not recapitulate them at present, but merely remark that this morbid state is very distinct in its features from idiotism, as it is likewise from insanity. For medical purposes these distinctions must be carefully observed, but the same division is not in all respects the most advantageous with reference to legal questions, in which an account is to be given merely of the degrees of incapacity. Such, at least, is the opinion of the author whose method we follow. At present, we are disposed to adopt his arrangement in this particular, and in the first place to divide mental affections into two departments, which may be distinguished as defects and diseases of the mind. The former class comprehends the different modifications and degrees of natural deficiency as well as those of dementia or decay; the latter, all the forms of insanity, whether moral or intellectual.

I. Mental Deficiency.

Mental deficiency includes all the degrees of intellectual weakness, from the slightest appearance of dulness or incapacity to absolute fatuity. Different modifications of mental weakness are included under this head, whether arising from natural imperfection in the organ of intellect, or the consequences of disease: they are arranged according to the degrees in which the mind is found to be defective in its operations.

Before we proceed to this arrangement, we must distinguish, with Hoffbauer, two marked differences in the character of mental deficiency. One modification of this state is termed *imbecility* (*blödsinn*), and the other stupidity (*dummheit*). The former is said to consist in a defect of *intensity*, the other in a want of *extensity*. By intensity M. Hoffbauer describes the energy with which a sound mind applies itself to judge with accuracy on the objects of reflection, or on the data already furnished by the senses and by perception; extensity is a similar energy directed externally to sensation and apprehension, or to the acquisition of ideas. The former defect renders the intellect unable to examine with sufficient exactness the data on which j dgment is to be exercised, the latter renders it liable to suffer some of these data to escape. M. Chambeyron, the French translator of Hoffbauer, objects to this distinction. He says that until we can determine in each kind of mental alienation the precise nature of that cerebral change of which it is the symptom, it is better to follow the method of Pinel; to observe what are the phenomena which are generally grouped together, and of each of these groups to constitute a distinct species; a principle of arrangement which may equally be followed in the distribution of mental as of other disorders. This observation points out the only sound and philosophical foundation on which nosological distinctions can rest, but to us it does not appear to lead justly to a rejection of M. Hoffbauer's attempt to discriminate the different forms of mental weakness. There is in fact, if we are not mistaken, a marked diversity among men as to the relative degrees of energy in their internal and external faculties, meaning by the former the powers of judgment and reflection, of reason, the faculties by which the mind decides on truth and falsehood, right and wrong, and in general of relations; and by the latter the ability for external perception and apprehension. When the whole constitution of the mind is weak, so as to render the individual barely competent to the business of life, these differences are the more striking and conspicuous. Many persons whose power of judgment is very deficient have a tolerable share of quickness in apprehension; others, on the contrary, (and these often appear much more defective than the former class,) are slow of perception, and let many things escape them which would be observed by ordinary men, yet they make occasionally shrewd remarks, and give tokens in their conduct which indicate a sagacity much beyond the measure of intellect which common observers ascribe to them. M. Hoffbauer is correct in distinguishing two classes among weak and half idiotic persons. One of these may be described as *imbecile* or defective in judgment, in the powers of reason and discrimination, while the other or *stupid* class show their deficiency chiefly in obtuseness or slowness of perception and apprehension, and in a consequent ignorance of external things and relations.*

That form of intellectual weakness which is distinguished by the term imbecility differs in several respects from stupidity or obtuseness of the mental faculties.

"In reference to the faculty of judgment, it may be observed that the stupid or obtuse person is more liable than the imbecile to form erroneous decisions; the latter experiences great difficulty in bringing himself to any conclusion. Secondly, the stupid person sometimes judges very correctly on subjects to which his attention has been

* Hoffbauer has explained his ideas on the nature of "*blödsinn* and *dummheit*" more fully in his Untersuchungen, th. i. s. 9.

strongly applied; occasionally he comes even more directly to a right conclusion than those who are possessed of superior intelligence. When he errs, it is through neglect of some of the considerations which ought to have formed the groundwork of his judgment, and he will say, in order to excuse himself, that 'he should never have dreamt of this or that circumstance.' To the imbecile the most simple act of judgment is difficult: for instance, a lady who said that she was twenty-five years of age, and had been married six years, could not, after many efforts, tell how old she was at the period of her wedding. Thirdly, the stupid man may often be induced to correct his mistake, some particular circumstance being suggested to him which leads to its detection. The imbecile man can scarcely rectify his error, being unable sufficiently to concentrate his attention on any particular subject. The stupid man has not this defect, but he views every subject on one side only, and is embarrassed by every complex idea.

"In relation also to memory, there is a decided difference between stupid and imbecile persons. The latter appear to be almost entirely defective in this faculty: the former recollect after a long interval of time some insulated circumstances or transactions. The reason of these peculiarities is the total want of attention to present objects which is characteristic of the one state, and the partial but concentrated attention to them which is observable in the other.

"Weakness of intellect displays itself in both these classes of persons, when their defect is in a high degree, by a propensity which they have to talk to themselves. This is most observable when the affected individual is alone or supposes himself to be so. In reality, we employ words not merely for purposes of intercourse, but as an instrument of thought, and the weakest intellects require their aid in the most perceptible manner. When the mind is morbidly weakened, the silent and unperceived or the mental employment of words is insufficient: they must be repeated more or less audibly. This practice is not uncommon with imbecile and stupid persons, but when in society they generally perceive its incongruity and abstain from it. If, however, such individuals talk to themselves, knowing themselves to be in the presence of other persons, it is a proof of greater deficiency.

"Another distinction between the stupid and imbecile is that the former imagines himself to be at least equal to other men in intelligence, whereas the imbecile is ever conscious of his state, and even exaggerates his defect.

"This difference between them is easily explained, as well as the results which it induces in their conduct. The stupid act rashly and without reflection; the imbecile can never come to a determination. Hence, also, the imbecile becomes cautious, timid, and even misanthropic, unless when assured of their security by finding themselves under the protection of persons of whose kind intentions toward them they are well convinced: to the guidance of such persons they give themselves up with blind confidence.

"The pusillanimity and misanthropy of the imbecile lead them to a species of devotion, if such it may be termed. Supposing themselves to be despised and ill-treated by men, they are led to apply for support to the common resource of the unfortunate. The stupid, more confident in themselves, fancy that they acquire merit by their devotions, or confer a favour on the divinity."

This account of the phenomena of mental weakness might suffice for ordinary purposes, but the deficiency exists in different degrees, and one stage in the approach to idiotism has results, in respect to social relations, which do not belong to a different grade in the same scale. M. Hoffbauer has for the first time made the attempt to define the gradations of mental deficiency as a basis for suggestions on the legal bearings of this state in particular degrees. It was hardly to be expected that he should accomplish this undertaking at once in a manner wholly free from error, and requiring no correction or improvement. The outline which he has sketched is drawn with great ability, and is evidently the result of extensive observation, assisted by no ordinary talent for generalizing phenomena and tracing their connections. The subject is so important that we shall incur the risk of being thought somewhat prolix, and give an abridged extract of this author's description of the five stages or degrees into which he divides the affection of imbecility (*blödsinn*), and the three degrees of stupidity or obtuseness (*dummheit*).

"The *first* degree of imbecility manifests itself in the incapability of forming a judgment respecting any new object, even when the necessary data are furnished, and the question is one which in itself presents no difficulty: in this degree of the affection the individual can very well judge respecting objects to which he is daily accustomed, and in familiarity with which he may be said to have grown up; he often shows, in the pursuit of his daily concerns, a minute exactness which appears to him a matter of absolute necessity. His memory is very limited; not that he absolutely loses the remembrance of things, but because he cannot apply his recollections according to his wishes. He scrupulously observes whatever he thinks becoming in his situation, because he fears to give offence in neglecting it. When he gives himself up to avarice, there is observed in him rather an apprehension of losing than a desire of accumulation. The propensity to talk alone, and the species of devotion to which we have alluded, is seldom to be met with in this instance, the former because the routine of daily occupations, above which the individual seldom raises himself, makes but small demands on his intelligence; the latter because his infirmity is not so remarkable in ordinary society as to render it a subject of general observation, and entail upon him frequent annoyance, and thus make him feel the necessity of seeking support elsewhere. He is very subject to gusts of passion, which nevertheless are as easily appeased as they are excited."

The preceding description will be found to coincide accurately with many cases of mental defect arising from original or congenital weakness of the intellectual faculties. We could furnish instances from our own observation which strikingly exemplify it. The statement given of the second degree belongs obviously to dementia or

mental decay, and will be found very accurately to describe many instances of senile dementia.

"In the *second* degree of imbecility the patient still judges and acts consequently with respect to subjects that are familiar to him, but even on those subjects it often happens that he is deceived, because, through a distraction which is a second nature to him, he forgets places, times, and circumstances. He observes so little what takes place or what passes around him, that he often fancies himself in a different spot from that in which he really is, mistakes strangers for persons of his acquaintance, confounds the present with the past, but more often with the future, and believes himself at home when he is at the house of another person.

"The individual affected with imbecility in the *third* degree is unfitted for all matters which require more than a mechanical mode of action, but he preserves sufficient intelligence to be aware of his weakness and the superiority of others with respect to the mental faculties. We may likewise remark in him that propensity to devotion and to misanthropy which we have mentioned above. His mind is not completely inactive, although it cannot raise itself to any high pitch; hence he has the propensity to talk to himself. He has not the power of seizing any idea so clearly as to impress it on his mind; hence a very marked defect of memory, and a propensity to pass rapidly from one topic to another. He is very irritable and suspicious, fancies a design to insult him where it is impossible, because his state yet permits him to feel and resent injuries; of which susceptibility those around him often take advantage to his annoyance.

"The *fourth* degree of imbecility is marked by a clouded state of the understanding and the memory, with a great insensibility, which nevertheless leaves the patient a confused idea of his weakness. He eagerly seeks excitement by various stimuli.

"In the *fifth* degree of imbecility there is a nullity of intelligence; the attention cannot be directed to any object; all the faculties whose activity depends upon the intellect are destroyed or oppressed. The phenomena which depend upon attention are wanting, and those which imply its absence take their place. The imbecile in this degree is insusceptible of passions, of joy, of grief, of pleasure, in a word, of every kind of moral feeling. He is even but little sensible of pain and other physical inconveniences. He only takes nourishment because it is given to him, like an infant; the natural wants, such as hunger and thirst, have no effect upon him. He has no memory, he has neither devotion nor the desire of talking to himself, which is observed in other imbecile persons, but which implies in them to a certain degree a consciousness of their state."

The fifth stage of imbecility thus characterized by Hoffbauer, is precisely the last grade of dementia or the fatuity which is the consequence of cerebral diseases. It has been more particularly described in the article INSANITY, under the distinctive term *Amentia*, appropriated to the last stage of the disease.

"Stupidity, generally speaking, is a defect less severe than imbecility, according to the definition that we have given of both. The slightest degree, however, of imbecility indicates an imperfection of the intellectual powers less severe than the greatest degree of stupidity.

"We admit in stupidity *three* principal degrees.

"In the *first*, the individual is incapable of judging and of self-determination, only when it is necessary to weigh opposing motives. Then he feels his incapacity, and has recourse to the intelligence of others, unless pride happens to prevent him, which is often the case. If he acts absurdly, it is often because he applies to his actions a rule good in itself, but the application of which requires other considerations.

"The subject of the *second* degree of stupidity forms a judgment accurately and often promptly upon things by which he is daily surrounded; but he commits serious errors whenever it is necessary to exert a certain vigour of judgment: he embarrasses himself in any train of reasoning, however simple it may be. His memory is perhaps faithful, but it is slow; he cannot, without great difficulty, express a complex idea, if it is the result of his own reflections, and has not been received from another. When his faculties have been somewhat developed by education, he is an obstinate partisan of any thing which is, as we say, good in theory but useless in practice; because he cannot observe the circumstances which distinguish particular cases, and appreciate them according to their just value. These two conditions are, however, indispensable, in order to make with propriety the application of general rules.

"In the *highest* degree of stupidity the individual cannot go beyond one single idea; and he must completely lose that one before he can pass to another. He is hence less capable of judging than the imbecile, because the comparison of several ideas is necessary to form a judgment. Individuals who are afflicted in the third degree of stupidity often express themselves in half-uttered words, return incessantly to the same subject, make known their ideas by sentences, short, incoherent, and unfinished, like children who can retain words, but do not know how to connect them together; they express often the subject and the attribute without connecting the one to the other by the affirmative or negative. If they wish to say 'the rose is beautiful,' they will say 'rose beautiful,' or only rose, or beautiful, according as the subject or the attribute strikes them most. Often they reverse the natural order of words, and say, for example, 'rose beautiful is;' and when they perceive an omission which they wish to repair, they become still more perplexed.

"With respect to legal relations, the first degree of imbecility may be assimilated to the second degree of stupidity, and the highest degree of the latter to the third degree of the former."

M. Esquirol has made objections to the minuteness and attempted accuracy of these distinctions. He thinks it difficult, if not impossible, to determine the exact limits of each stage. The endeavour to lay down rules with accuracy scarcely attainable in practice may sometimes impose unnecessary difficulties. This is undoubtedly true, and perhaps it may be admitted that the modifica-

tions and degrees of which Hoffbauer's arrangement consists are more numerous than they ought to be. Yet the necessity of adopting some method of this kind is obvious, unless we determine to regard mental deficiency as an absolute state, and admitting of no gradations. Experience proves more and more the error of such a proceeding. The want of some rule by which the various degrees of incapacity may be measured, and the relations of each determined, has often been felt;* and M. Hoffbauer's arrangement will at least be useful as furnishing a scale to which approximations may be made in particular instances. M. Esquirol seems to suppose that Hoffbauer intended only to describe different degrees or varieties of dementia; but this appears to us to have been the case only in some instances. The first or lowest stage both of imbecility and of stupidity are clearly intended for, and strikingly characteristic of, natural weakness in some of its varieties.†

We proceed now to the practical application of these distinctions, but in this we must be satisfied with suggesting a few of the most important considerations.

"In matters of criminal accusation, all legal culpability is annulled when it is proved that the party labours under imbecility amounting to the third degree, or even nearly approaching it. Imbecility in the first and second degree may either annul or weaken culpability, or leave it unaffected under different circumstances. Ignorance of the law and of the illicit nature of actions may sometimes be alleged as excuses in criminal accusations, in the instance of imbecility amounting to the first degree. But this plea can only be allowed to be valid under one of the two following conditions: — 1st, when the law which has been violated by the imbecile neither forms part of general relations which concern himself as well as other members of society, nor belongs to his own particular habits or circumstances: 2dly, when the action forbidden by the legislator is not contrary to the law of nature.

"The second degree of imbecility may lessen or destroy culpability in cases in which the first degree leaves it entire.

"In the first degree of imbecility, inattention or absence of mind, want of foresight, &c., are not considered as excuses when they have regard to objects universally known, as to fire, or to those which are familiar in use to the imbecile, as the tools, &c. of his profession. In all other instances his fault loses the degree of culpability which belongs to it, according to the expression of jurists, *in abstracto*. This is also the case when the act is the result of sudden anger or fear, to which weak persons are prone.

"The imbecile in the second degree has less responsibility than in the first. His incapacity is greater, as likewise is his proneness to sudden emotions.

"Similar considerations affect the responsibility of persons labouring under stupidity, when it passes the middle degree above described. In fact, the latter being incapable of extending their thoughts to several objects at the same time, must omit many considerations of which intelligent persons never lose sight. Such an individual is so much the less responsible for his actions, as he is known to be incapable of the reflection which might lead another to rectify his mistakes.

"The principles established in reference to criminal law, on the ignorance of the parties, are applicable in civil law to the question — whether an individual is in a condition to recognise the illicit nature of an act by which he has trespassed on the right of another. In imbecility in the first or second degree, ignorance of the law may be pleaded as excuse under circumstances analogous to those before alluded to.

"All the arrangements which the law authorizes or prescribes in regard to imbecile persons, are founded either on their own interest or on that of others, and have for their object the personal security of either party. These arrangements refer, 1st, to the appointment of a *tutela* for the administration of the property of the weak or idiotic person, and of a *curatela* for the care of his person; 2dly, to seclusion, when it is required for preventing dangers likely to accrue to society or to the individual, from his unrestrained enjoyment of personal freedom. All the measures judged necessary for his security and for the protection of society, must be taken with as much mildness as possible.

"An imbecile person, whose affliction reaches the third degree, can no longer be judged competent to the care of his own property: this may be observed *à fortiori*, if his disorder passes that degree. But in the appointment of a tutela, regard must be had to the necessity, greater or less, of such protection, and especially to the particular character, habits, inclinations, &c. of the individual. It must be considered whether he is likely to commit actions which, though indifferent in themselves, may occasion public offence, or whether an excessive liberality or ruinous prodigality may not expose him to dissipate the property that may be left at his disposal.

"The administration of his property should be left to the imbecile in the second degree, and a curator should be appointed for him under particular circumstances, as, for example, when his character calls for such an arrangement, and when some interests are at stake which require practical intelligence, and especially constant attention. With such exception, it is unjust to deprive him of the management of his affairs. The inconveniences to which he may contingently be exposed cannot be compared with the certain annoyances connected with a tutela, and some reliance may

* Dr. Haslam has made this remark, but no attempt to furnish a scale of distinction. See Haslam on Medical Jurisprudence, as it relates to Insanity, p. 60. Any person who has attended inquests must be aware that the want of some certain rule or principle, by which both physicians and those who have to give the verdict may be assisted in forming their judgment, is often felt.

† Hoffbauer's distribution of the forms and degrees of mental weakness, which has obtained great celebrity in Germany, is highly commended by Professor Heinroth, (Störungen des Seelenlebens,) who, however, contemplates the subject in a different point of view. Heinroth suggests an additional modification, consisting in (willensschwäche) weakness of will or irresolution, and excessive timidity and fickleness of disposition; but this case can never become a matter of legal consideration. It is even questionable, as Heinroth observes, whether (dummheit) stupidity, as above defined, can ever do away entirely all moral responsibility.

be placed in general on the vigilance which self-interest calls forth even in defective minds.

"Persons imbecile in the second degree are more subject to act without reflection than those whose defect belongs to the first or the third stage. The former are rather irresolute and timid than precipitate in action, and the latter too negligent and inactive. Hence, though in the second degree imbecility does not generally authorize the appointment of a *tutela*, it often requires that individuals should be subjected to an especial *surveillance*.

"The imbecile whose infirmity does not exceed the first degree cannot justly be subjected to a tutela, or to any particular surveillance, except under circumstances in which his inclinations or habits, his family, relations, or fortune, or the affairs under his management, require such an arrangement.

"What has been observed in respect to the degrees of imbecility may be applied to stupidity, on the principle above laid down. Only it must be remembered that this last infirmity renders individuals more liable to rash and hasty actions than does imbecility.

"Imbecile persons in the third degree are evidently incapable of making wills; as their state renders them competent only to actions, which, if not unreasonable, are without reflection. The case is not so in the instance of imbeciles in the first and second degree, even though under certain circumstances, before adverted to, they may occasionally be subjected to a surveillance or even to a *curatela*. The object of this curatela is to protect them from injuries which they might bring upon themselves if left to their own discretion, and to prevent engagements which they might contract and be unable to fulfil. These considerations are not, however, reasons for depriving them of the power of making a will. By a testament they might deprive those who would inherit *ab intestato*, but they prejudice no formal right. Besides, a testament does not require the same intelligence as the administration of property: it only depends upon a single arrangement, for which the testator has sufficient time for deliberation."

To this last opinion of M. Hoffbauer, it is objected by M. Chambeyron, that by the simple appointment of a tutela the imbecile person is assimilated to a minor, and declared incapable of any civil act, except under some particular circumstances, and when the authentic consent of the tutor may authorize him to contract. Why then, it is inquired, should there be any exception for the right of testating? The author has given a satisfactory reason why this right should be preserved inviolate in certain instances, namely, that individuals may and do retain the requisite degree of intelligence for entering into the arrangements in question, though in other respects in a state which renders the appointment of a guardian, or some especial *surveillance*, advisable. The incongruity pointed out by M. Chambeyron has respect to positive institutions, and the observation of M. Hoffbauer is founded on general principles.

We shall here terminate the consideration of mental weakness or defect, and now proceed to the second division of our subject, namely, Diseases of the Mind,—a term which we adopt for the sake of convenience, though, on the ground of strict propriety, objectionable.

II. Diseases of the Mind considered in relation to Jurisprudence.

1. Of Intellectual Derangement or Mental Illusion.—*Monomania and Mania.*—Professor Hoffbauer adopted an ingenious, though erroneous, idea as to the nature of these diseases. On this he has founded some practical conclusions, of which the validity is very doubtful; they deserve, however, for reasons which will appear, a few moments' consideration. Mental illusion (wahnsinn) consists, according to him, in a loss of that due proportion which, in the sound state of the mind, the powers of sense and perception bear to the influence of imagination. The influence of imagination may become excessive in two ways; first, by increased intensity or exaltation of this faculty, the other powers remaining the same; or, secondly, by depression of the latter, while the faculty of imagination remains unchanged. The former is monomania, in which, as the author supposes, the mind is not destroyed or generally affected. The latter is mania, and in this the powers of the understanding, perception, apprehension, are greatly impaired.

No practical error is likely to arise from this opinion, as far as it respects the nature of mania. Persons who are generally deranged or raving mad, cannot be supposed by any one to be accountable for their conduct, or capable of managing their affairs. No dispute exists among jurists or physicians on this subject. The state of maniacs is, in general, too manifest to admit of any doubt. The lunatic perceives the objects and persons who surround him, but his imagination transforms them, and they are mistaken by him as to their nature and identity. "Hence in civil law the acts of such an individual manifestly lose all their consequences, and can neither convey any right to another, nor place the agent himself under obligation. In criminal law he is discharged from all responsibility, and consequently from all culpability; since what he wills to do in his imaginary situation is not what he would do in his real situation, were he only aware of the latter. This state of disease fully justifies the placing an individual under a tutela, and the disposing of his person in that way which shall appear most conducive to his recovery, or, in hopeless cases, to his security and comfort."

It will be apparent to those who entertain a correct opinion as to the nature of monomania, or partial derangement of the understanding, that a great part of this reasoning applies almost equally to persons affected by that form of disease. But here we find Professor Hoffbauer's theory leading him into error, an error which is not peculiar to him. As his opinion is common to many, and the inference to which it has led him is by no means a matter of indifference, we shall cite some of his observations, and presently add the comments of a practical physician, the powers of whose acute and penetrating mind have been directed to this subject.

Hoffbauer supposes that, in partial insanity characterized by hallucinations, the representation

of unreal objects, or the illusory transformations of existing ones, such illusions can only pervert the judgment when the affected train of ideas is brought into play; and that on matters unconnected with this illusion, the individual is to be considered as a sane man. "In this relation, therefore, insanity cannot be recognised by the law. In civil law all the acts of the party preserve their validity, and in criminal law their culpability." In fact, there is no reason why a man who thinks he has legs of glass, and in other respects is in possession of all his faculties, should not be capable of contracts, and responsible for illegal acts which have no connection with the subject of his madness. Such a species of insanity seldom prevents a man from managing his own affairs, or undertaking any legal relations for others. Swedenborg, so celebrated by his visions, who was confessedly a madman, fulfilled the duties of his office in so distinguished a manner, that the king of Sweden ennobled him. The author knew a doctor in laws who had taken it into his head that all the freemasons had entered into a league against him. This person, who in other respects was perfectly sane, held with high credit a chair in an university.
